III.—SOLUTION OF CONTINUITY FROM ALTERED POSITION OF PARTS.

(CONTINUED.)

B.—OF RUPTURES.

1109. *A Rupture* (*Hernia*, Lat.; *Bruch*, Germ.; *Hernie*, Fr.) is the protrusion of an intestine from its own cavity into the surrounding cellular tissue, or into another cavity. Ruptures are therefore distinguished, according to the three cavities of our body, as *ruptures of the belly*, *of the chest*, and *of the head*.

I.—Of Ruptures of the Belly.

First Chapter.—OF RUPTURES OF THE BELLY IN GENERAL.

1110. Ruptures of the Belly (*Herniæ abdominales*) may occur throughout the whole extent of its wall, if this give way or be torn. Most commonly they occur at those parts of the belly where there are already openings for the passage of vessels, nerves, and so on.

1111. According to the various parts at which ruptures are formed, they are distinguished as, 1, *Inguinal*, which pass through the inguinal canal; 2, *Femoral*, beneath POUPART's ligament; 3, *Umbilical*, through the umbilical hole; 4, *Thyroid*, through the thyroid hole; 5, *Ischiatic*, through the ischiatic notch; 6, *Ventral*, through the wall of the belly, the holes already mentioned excepted; 7, *Perinæal*; 8, *Vaginal*; 9, *Rectal*, when the rupture protrudes at the *perinæum*, in the *vagina*, or in the *rectum* (1).

Inguinal, femoral and umbilical are the most common ruptures, the others are more rare.

[(1) To this list must certainly be added *Phrenic* rupture (*Hernia diaphragmatica.*) And English Surgeons speak also of *mesenteric*, *meso-colic*, and *meso-rectal* ruptures, although strictly speaking they do not resemble true ruptures in leaving their proper cavity, but they burst through parts which have no natural opening for their passage and thus become displaced.—J. F. S.]

1112. Those intestines of the belly which on account of their position and connexion are least fixed, protrude most commonly, as the *omentum* and the small intestines, more rarely the large intestines, the stomach, the bladder, the internal female generative organs, and the like. Parts may be in the rupture which in their natural place are very far from it. These are either drawn down by the protruding intestines, with which they are connected, or by the descent of the *peritoneum*, to which they are attached. According to the intestine which ruptures contain are they distinguished as *intestinal*, (*Hernia Intestinalis*, Lat; *Darmbruch*, Germ.; *Enterocele*, Fr.,) *omental*, (*Hernia Omentalis*, Lat.; *Netzbruch*, Germ.; *Epiplocèle*, Fr.,) *ventricular*, (*Hernia Ventriculi*, Lat.; *Magenbruch*, Germ.; *Gastrocele*, Fr.,) *vesical*, (*Hernia Vesicæ*, Lat.; *Harnblasenbruch*, Germ.; *Cystocele*, Fr.,) and so on. Several intestines may be contained at the same time in one sac, as for instance intestine and *omentum*, (*Darmnetzbruch*, Germ.; *Entero-epiplocele*, Fr.,) and the like.

1113. When the intestines of the belly are protruded into a rupture, they are usually enclosed in a sac, (*saccus herniosus*, Lat.; *Bruchsack*, Germ.; *sac herniaire*, Fr.,) which is formed of the lengthened *peritoneum*. In rare cases only is this sac deficient; for instance, when the rupture is caused by great violence, or after previous wound of the wall of the belly, or after the application of escharotics for the radical cure of the rupture. The sac may also be torn, or destroyed by absorption. If intestines protrude, which are not enclosed in the *peritoneum*, for example, the bladder (1) and *cæcum* (2), there is not any sac; but if they be much protruded, they draw down the *peritoneum* connected with them, and thereby form a sac into which other intestines may pass.

[(1) In regard to vesical rupture, it is certainly just possible that the bladder may rise to the internal abdominal ring, and thrusting up the *peritoneum* from that opening, may protrude some part of its body uncovered by *peritoneum* through it, and this may continue to descend through the inguinal canal and form a rupture without a peritoneal or true hernial sac. But such state of things is highly improbable, and in the two cases of vesical rupture in the museum at St. Thomas's is certainly not so, for in this preparation it is the *fundus* of the bladder, that part of the organ most likely to be protruded, with its peritoneal covering which has passed through the abdominal ring into a distinct peritoneal sac, which from its appearance probably belonged originally to a rupture of the intestinal or omental kind.

(2) I do not think that the *cæcum* would often protrude as a rupture without having a peritoneal sac, more than the bladder, and for nearly the same reasons. There is, however, in the Museum at St. Bartholomew's a *cæcum* carried into the *scrotum* with a partial sac, and I have also had one case in which I suspect the *colon* did. But

that it does descend into a true hernial sac is beyond doubt, for in the museum of the Royal College of Surgeons of England, there is an instance of the lower end of the *ileum*, the *cæcum* and its appendage, and part of the ascending *colon*, with a large piece of *omentum* in the sac of a large oblique inguinal rupture. There is also another preparation, in which the lower end of the *ileum*, with the *cæcum* and its appendage, are in the sac of an inguinal rupture, and the extremity of the appendage is attached to the bottom of the sac. In St. Bartholomew's museum there is a scrotal rupture (with hydrocele in front) containing *cæcum* and *colon*. Also a femoral rupture, in which there is small intestine, a portion of the sigmoid flexure of the *colon* and *omentum*.

A very rare instance of protrusion of the vermiform appendage of the *cæcum* in a strangulated inguinal rupture is given by Taramelli (*a*); the appendage alone was found in the sac, increased to four times its ordinary size, and an indent at its junction with the *cæcum* showed the seat of strangulation. The patient did well.—J. F. S.]

1114. The cavity of the hernial sac is connected with the cavity of the belly by an opening, the *mouth of the sac*; the narrow part between this opening and the greater extent of the sac is called the *neck of the sac*; the remaining part the *body*; and the blind end, the *bottom* of the hernial sac. The sac is furnished with different coverings according to the difference of place where the rupture exists; on its outer surface it is slightly connected with the surrounding cellular tissue, and therefore the sac remains external when the intestines have been returned.

1115. The hernial sac is very frequently subject to changes. The *peritoneum* of which it is formed usually retains its natural condition, and when in old ruptures it thickens, and is found to consist of several layers, the cause of these changes, for the most part, rests on the thickening of the cellular tissue, which covers the outer surface of the sac. The substance of the *peritoneum* itself, however, often thickens and even becomes almost cartilaginised (1). These changes are the result of the irritation and pressure to which the sac is subjected, by the passage forwards and backwards of the intestines; they therefore occur especially in old ruptures which cannot be properly kept up by the truss, and mostly at the neck of the sac. If by contraction of the neck of the sac, or by thickening of the cellular tissue covering it, a narrowing be produced, it may in the gradual increasing volume of the rupture descend, and thus may several strictures be formed in the body of the sac (2). These changes are not always relative to the size of the sac. In large ruptures the sac is often very thin, even so thin, that the peristaltic movement of the intestines can be perceived through the external skin. In large umbilical ruptures the hernial sac is often very thin, and in small femoral ruptures very thick. Swellings also may form on the sac from degeneration of the cellular tissue (3).

[(1) In the museum at St. Thomas's, there is a preparation of a femoral hernial sac converted into bone.

(2) I do not agree with Chelius's statement on the causes of stricture in the body of the hernial sac. As regards the descent of the neck, or more properly, the mouth of the sac, into its cavity, so that the stricture is not at the immediate opening into the cavity of the belly, but at a less or greater distance below it, so far as I have had opportunity of observing, it is of great rarity. I have only once seen it, and that during last spring, in a case of oblique scrotal rupture, in a young man, which had existed for several years, and in which during the operation an extremely tight stricture was found very high up. This I divided upon a director sufficiently to admit my forefinger freely into the cavity of the belly; but with all the pains I could take I was unable to return the gut. After many unavailing efforts I cut through the tendon of the external oblique muscle and the other coverings of the upper part of the sac, till I brought its strictured mouth completely into view, which immediately explained the difficulty. The mouth of the sac had descended into its cavity, doubling the neck upon itself, so that a circular blind pouch about half an inch deep, encircled the mouth, which had the same relation to the sac as the mouth of the womb has to the *vagina*, and its margin had become so

(*a*) Omodei, Annali Universali di Medicina, vol. lxxv. p. 430. 1835.

firmly and narrowly thickened, that it resembled a ring of whipcord. Into this blind circular pouch the intestine had been thrust at every attempt I had made for its reduction, and thus both escaped, and shut up the mouth of the sac. The finger could be passed into the cavity of the belly, as freely as before; but I thought it best to divide this cord-like edge and the indoubled neck, so as to render the reduction more easy, and such was the result. The patient did well.

As to the production of strictures in the body of the sac, I believe that generally these depend much more frequently on bands of adhesive matter having been thrown out under inflammation of the peritoneal sac itself, from some accidental cause or other, rather than from thickening of the cellular tissue external to it, which, however, may take place, as I have seen it do, occasionally producing, not indeed actual bands or strictures, but merely an hour-glass contraction of the sac.

(3) Sometimes a hernial sac is contracted in its middle and assumes an hour-glass shape; such a case I have operated on, but it did not produce any confusion. Occasionally, however, it may, as is shown in a preparation at St. Bartholomew's, in which the sac of a congenital rupture has an hour-glass contraction at the abdominal ring, and part of it is without, whilst the other part is within the belly, and into the latter portion the gut had been returned, and left.—J. F. S.]

1116. The size of ruptures is very different. Often the rupture contains the greatest part of the intestines of the belly; often is it so small that it can be discovered only with the greatest care. Of the intestine itself there is protruded either an entire loop or only a portion.

1117. Several ruptures often occur in the same subject. Rarely are several, each having its own sac, at the same spot; more frequently, by the protrusion of the urinary bladder, or some other intestine only partially covered with *peritoneum*, so that the latter is drawn with it, a hernial sac is formed into which the intestines pass. A double hernial sac is very rare, and indeed possible only in inguinal hernia, where a special sac containing intestines may drive into the vaginal tunic of the testicle, when its mouth has remained open.

Bransby Cooper (*a*) mentions a case of two inguinal ruptures on the same side; the contents of the hinder, larger sac, which remained external, were returnable into the cavity of the belly, but the front smaller sac with its contained intestine had been easily returned into the belly, by the *taxis*; he does not, however, explain, how it happened that this thrusting up of the sac and its contents had been effected which is one of the most curious points of the case.

[Lawrence says, there is a "kind of double rupture not ascertainable in general, except by examination after death, or in operating, viz.: two sacs passing through the same opening; this may happen in external or internal inguinal or crural *herniæ*. There are instances of even three sacs, particularly in inguinal *herniæ*." (p. 13)

As regards the number of hernial sacs, Astley Cooper says: "Two herniary sacs have been stated to pass behind the same crural arch; but although I would not be understood to deny their existence, I have not seen an example of sacs having two separate orifices into the cavity of the *abdomen*; but I have known one hernial sac descending into the sheath for the crural vessels, and crossing the anterior part of these, and another portion of it quitting the sheath and extending in the usual direction upon the thigh." (p. 4.) He also gives an example of six hernial sacs:—"Two of the sacs upon each side were placed between the umbilical and epigastric arteries; and one on each side is situated between the remains of the umbilical arteries and the *pubes*. They passed between the tendinous fibres of the *transversalis*, which they had separated, and entered the adominal rings, after which they were covered, as usual, by the *fascia*, which is extended from the external oblique muscle over the spermatic cord." (Explanation of pl. x. pt. i.) And he observes, that after wearing a truss, "although the original sac may be completely shut at its mouth by adhesion or perfect contraction, it is possible that another sac may be formed contiguous to the first." And he gives an instance, in which "two hernial sacs were found side by side, one open and capable of containing the bowels when protruded, the other contracted so much as not to admit a goose's quill." p. 23.)

Morgan (*b*) had a remakable instance of a pouch formed at the mouth of the *tunica*

(*a*) Guy's Hospital Reports, vol. iv. p. 326.

(*b*) Astley Cooper, above cited, p. 83.

vaginalis, in consequence of partial adhesions of the membrane. The patient had scrotal rupture on the right side, accompanied with symptoms of strangulation. It was reduced with great ease, by gentle application of the *taxis*. The symptoms, however, continued, and on the following day "a small tumour was perceptible in the course of the inguinal canal." On the third day he was worse, and an operation having been decided on, "after dividing the integuments, superficial *fascia*, and cremaster, in the usual manner, what appeared to be hernial sac was brought into view; this was laid open, and on the operator introducing his finger, it readily passed through the external ring into the inguinal canal; here an unnatural projection could be felt, but no gut was found, nor could the finger be passed into the *abdomen*. The inguinal canal was then exposed by slitting up the tendon of the external oblique, and the sac before mentioned was more extensively opened, still no intestine could be found, and no communication appeared to exist between the sac and the abdominal cavity. A substance was felt in the canal which resembled a thickening of the cord." Nothing more was done, and he died on the second day after the operation. Upon examination, the part "supposed to be hernial sac, and opened as such, was the reflected portion of the *tunica vaginalis*, into the cavity of which the finger had been introduced." The tumour in the course of the inguinal canal was a hernial sac, behind the cord, and containing a portion of strangulated intestine of a very dark colour, and with a large gangrenous spot. This *hernia*, had by its pressure, prevented the entrance of the finger into the belly. "Just below the opening of the *tunica vaginalis* into the *abdomen*, was situated the mouth of a preternatural pouch, which extended downwards and inwards behind the *fascia transversalis* in the direction of the crural ring. It was into this pouch that a portion of the *ileum* had descended and had there become strangulated. It seems probable that at the time of the man's admission into the hospital, a large portion of intestine had descended into the cavity of the *tunica vaginalis*, the cavity of which bore all the appearances of an old hernial sac. This, however, was easily returned, while the portion of bowel contained in the other pouch, remained unreduced and suffering under strangulation, caused the symptoms which ended in the patient's death." (p. 83.)

In the museum at St. Bartholomew's there are two beautiful preparations, one exhibiting two inguinal hernial sacs, on the left side, close together and of considerable length, the mouth of the outer very small; the other femoral, in which there are two distinct sacs and orifices, the outer descends beneath the semi-lunar edge of the *fascia lata*, but the inner is so small that it scarcely protrudes.

Sometimes the sac of a rupture is divided vertically into two, probably by adhesive inflammation. I have operated on one such scrotal case. In St. Bartholomew's museum there is a common scrotal and also a congenital scrotal rupture of similar kind.

In rare cases, one or other side of the sac of a femoral rupture is burst, and a part of its contents are protruded in either direction, so as to form a seeming second sac. I have had three cases of this kind, which will be hereafter noticed, and the case mentioned by ASTLEY COOPER, in which "one hernial sac descended into the sheath for the crural vessels and crossed the anterior part of these, and another portion of it quitted the sheath and extended in the usual direction upon the thigh," (p. 4), I believe to be of similar kind. Neither of these, however, are to be confused with the case described and figured by BRANSBY COOPER.—J. F. S.]

1118. Ruptures are either *free*, or *reducible*, (*frei*, *beweglich*, Germ.; *mobile*, Fr.,) when they return of themselves, or can be returned by moderate pressure; or *irreducible*, (*unbeweglich*, Germ.; *immobile*, Fr.,) when their return is impossible, the cause of which lies in the *adhesion of the intestines together* or *to the hernial sac*, in the *strangulation* or *other change of the parts found in the rupture*.

1119. As regards their origin, ruptures may be divided into *original* (*Herniæ congenitæ*, Lat.; *angeborne Bruch*, Germ.; *Hernie congénitale*, Fr.) and *acquired* (*Herniæ acquisitæ*, Lat.; *erworbene Bruch*, Germ; *Hernie acquise*, Fr.); in the first case the intestines pass through the processes of the *peritoneum*, which remain open; in the second, after the processes have closed or at some other place.

1120. The *causes* of abdominal ruptures are *predisposing* and *occasional*. Predisposition to rupture, which may be either original or acquired, consists in a relaxation and weakness of the wall of the belly, and in greater enlargement of its natural openings. It may be produced by corpulency, by great extension of the wall of the belly during dropsy or pregnancy, by quick emaciation, by scars after wounds, especially when the injury of the abdominal wall has been connected with bruising; by diseased changes of the intestines of the belly, by loading them with coarse food, by immoderate use of relaxing drinks and the like.

The occasional causes are all kinds of violence which produce great contraction of the wall of the belly and depression of the diaphragm, whereby the intestines are forcibly thrust against the former; for instance, a violent thrust or blow upon the belly, tight lacing, violent exertion on lifting heavy weights, in breathing, coughing, vomiting, in childbirth, peculiar positions, and so on. The greater the predisposing causes to rupture, the less requisite are the occasional causes; in great disposition to rupture, they often occur without any assignable occasional cause.

In many countries ruptures are very common, and their causes seem to depend on climate, on the mode of living, and on the particular exertions to which the inhabitants are subjected.

Ruptures occur more frequently in men than in women, and more frequently on the right than on the left side (1).

[(1) Lawrence has given the following curious statistical account of ruptures:—

"The comparative number of the different kinds of ruptures, and the relative frequency of the complaint generally, as well as that of its various forms in the two sexes, and at different periods of life, are exhibited in the following statement, extracted from the register of the patients relieved by the City of London Truss Society within twenty-eight years:—

In 83,584 patients, 67,798 were males, and 15,786 were females.

Males.	Females.				
14006	511	left inguinal	39419 inguinal	45629	single

Recherches sur les Causes et l' Anatomie des Hernies abdominales, p. 9, note.”]

1121. The following are generally the *symptoms of a reducible rupture of the belly*,—a swelling of quick or gradual production, not painful, elastic, of different form according to the opening by which it protrudes, on the surface of which the skin is unchanged, which can be returned by sufficient pressure, which returns of itself when the patient lies on his back, but after any exertion in coughing, sneezing, and the like, also after meal-time again protrudes or enlarges. It is accompanied with symptoms of disturbed intestinal functions, as sluggish bowels, rumblings in the bowels, belchings, disposition to vomit, dragging pains in the belly, and the like, which symptoms subside if the swelling be reduced, and afterwards the bowels are usually relieved.

If the rupture be small and deeply situated, the *diagnosis* is often difficult, and must be determined by close examination, by consideration of the origin of the swelling, and by all the existing symptoms.

1122. Decision as to the parts contained in the rupture is often very difficult, often even impossible, on account of the different changes which the parts themselves and the coverings of the rupture undergo.

[Chelius's observation, in reference to the difficulty or impossibility of distinguishing intestinal from omental rupture, is most fully borne out by practical experience, so that few persons are so hardy as to prognosticate the contents of a rupture-sac till it is opened.—J. F. S.]

1123. The *intestinal rupture* is characterized by a swelling more regular on its surface, elastic, which enlarges when the intestine is loaded, and in returning affords a gurgling noise (1), often felt in the swelling by the patient himself, and by the simultaneous symptoms of stoppage of the passage of the stools.

[(1) This gurgling noise is often entirely independent, I believe, of intestine, and caused by the quantity of fluid contained in the sac. And from the same cause arises a symptom which often puzzles a young Surgeon; to wit, the seeming reduction of a large portion of the contents of the sac, with a gurgling noise, whilst the remaining contents cannot be returned; and on the removal of the fingers, the rupture reacquires its original size, but admits of the same diminution, by pressure, only again to recover its bulk when the efforts at reduction are given up. This is very easily explained, as the fluid contained in the sac being pressed, squeezes between the sac and its contents into the cavity of the belly, although the intestine or *omentum* is so firmly grasped by the stricture that it cannot be returned.—J. F. S.]

1124. The *omental rupture* feels doughy, irregular, often rope-like, has a more cylindrical form with a broader base, is more slowly developed, is more difficult to reduce, is unaccompanied with any gurgling, and produces a heavy dragging upon the stomach.

1125. *Vesical rupture* is distinguished by the swelling fluctuating, enlarging, and becoming tense, if the patient retain his urine, and diminishing when he discharges it; and by pressure on the swelling exciting a disposition to void the urine. Frequently after making water, the tumour does not diminish, but the patient does not feel any disposition to urine, when it is pressed. As the bladder is always more or less dragged or pulled, the patient has a frequent disposition to make water; frequently the urine is completely retained, and in introducing a catheter, it must be observed that it be conducted in a peculiar manner into the bladder. If the vesical be complicated with omental or intestinal rupture, the symptoms are confused. Not unfrequently a stone is formed in the protruded part of the bladder.

1126. As to the other intestines which may be in the rupture, *the position of the rupture*, *its condition*, and the *disturbed functions of the contained parts*, afford the key. If several parts be together in the rupture, these symptoms are confused.

1127. Ruptures are always extremely important diseases. If they be left alone, and their neighbourhood be undisturbed, they always increase; the local and general inconveniences become greater, and the intestines may descend in such quantity into the rupture, that the greater part of them may rest in it. By the changes produced in the hernial sac (*par.* 1115) and the contained parts, the return of the rupture is rendered impossible, or strangulation is produced.

1128. The intestines contained in the rupture, may, in consequence of previous irritation, adhere to each other, or with the hernial sac, and the adhesion may be either a mere sticking together with a gelatinous mass, or it may be fibroid, or of a fleshy character, and may take place often only at certain parts, often to a great extent, so that all the parts of the rupture are consolidated into one mass. Omental ruptures grow together more readily than intestinal.

The adhesion of the hernial sac with the intestine, must be distinguished from those adhesions with the sac, which have existed before the production of the rupture, between the *peritoneum* and the intestines, in which the parts lying in the rupture, are, in the same way, attached to the sac, as it was earlier in the belly.

1129. The portion of intestine lying in the rupture, is generally thickened, and often considerably narrowed (1). This thickening of the tunics of the intestine may depend on the great development of their muscular coat, consequent on violent straining, for the purpose of driving forward its contents, in the obstructed return of the blood, or in the deposit of fibrine.

The *omentum* is very frequently very much changed in reference to its structure and form; it is usually thick and hard at the neck of the sac;

often rope-like, often rolled up into a hard lump; often is its bulk very much increased, beset with growths, and often exceedingly hardened.

[(1) I do not think that the protruded intestine is often either thickened or narrowed. The thickening which is sometimes observed in a strangulated gut, is of two kinds. The less important is when in consequence of strangulation, serum only is effused into the cellular tissue connecting the intestinal coats without other alteration, speedily subsides on the division of the stricture, and is not to be feared. The other kind, in which the cellular tissue of the gut is filled with adhesive matter, the result of a slow inflammatory action, and the intestinal wall acquires a thickness of the eighth of an inch or more, does not subside when the strangulation is removed, has a doughy feel, and is of a dirty reddish white colour, is a very dangerous symptom of the disease, and leads to the anticipation of an unfavourable termination of the case.—J. F. S.]

1130. When by a disproportion between the parts contained in the rupture, and the parts containing them, the communication between the belly and the rupture is arrested, *strangulation* (*Strangulatio*, Lat.; *Einklemmung*, Germ.; *Etranglement*, Fr.) ensues. The *causes* producing this disproportion are, increased protusion of the intestine in any exertion, overfilling of the intestine in the rupture with stools, intestinal gas, foreign bodies, and the like, consequent on overloading the stomach with food difficult of digestion and flatulent; growth of the protruded intestine, inflammatory swelling, degeneration of the *omentum*, and spasmodic affection of the intestinal canal.

1131. The seat of strangulation is either in the *opening into the belly*, through which the rupture has been produced (the *mouth of the rupture; Bruchpforte*, Germ.) or in the *hernial sac itself*.

1132. The *aponeurotic parts*, which form the abdominal mouth of the rupture, produce the strangulation of the parts protruded in great quantity, or increased in volume, never by *active* contraction, but because they do not yield any more, and by means of their elasticity, endeavour to return to their natural condition. Only in (external or oblique) inguinal ruptures, does a narrowing of the mouth of the rupture, by contraction of the wall of the belly, where the fibres of the internal oblique and transverse muscles surround the neck of the sac, seem possible to be produced.

1133. In the *hernial sac*, the confining part is either at the neck, or at various parts of its body, by narrowing and strictures which form in it, (*par.* 1115,) or it tears, and the intestines escaping through this opening become strangulated.

1134. The determination of the seat of the strangulation is often difficult, often impossible. The following circumstances may direct the practitioner:

Firstly. In a rupture which quickly arises from severe violence, or where, with little extensibility of the opening by which it has escaped, a large quantity of intestine is suddenly protruded, the unyieldingness of this opening is, for the most part, the cause of the strangulation. The hernial swelling does not spread upwards above the external abdominal ring, in inguinal rupture, the inguinal canal is throughout its whole extent yielding and free from pain; the pillars of the outer ring are stretched (*a*).

Secondly. That the strangulation is at the neck of the sac, as is most frequently the case, at least in inguinal ruptures, may probably be supposed, in ruptures which having been long kept up by a truss, suddenly protrude; when the aperture through which the rupture protrudes, not stretching, the hernial swelling, although very tense, is reducible, and in

---

(*a*) Dupuytren, De l'Etranglement au collet du sac herniaire; in his Leçons orales de Clinique Chirurgicale, vol. i. p. 557.

the attempt to return it behind the abdominal ring, a swelling is formed. The inguinal canal is full, hard, tense, painful, and presents to the feel a cylindrical swelling.

Thirdly. Tearing of the hernial sac, or the inflammatory affection of the parts lying in the rupture, may be supposed to be causes of the strangulation, from the violence with which they operate upon the rupture itself; and, in tearing the hernial sac, by the changes in its form which the hernial swelling undergoes from the projection of the intestines into the opening of the sac (*a*).

Fourthly. The overfilling of the intestines with intestinal matter, causes strangulation, mostly slowly, in old ruptures, by its gradual collection, or by overfilling the stomach. According to Malgaigne, never does solid matter, but only intestinal gas collect; the true ground of strangulation is inflammation, which is consequent on such ruptures.

Fifthly. The growth of the intestine itself, and the strangulation resulting therefrom, cannot be ascertained previous to operation.

Malgaigne's supposition, that the strangulation is not produced by the ring, but at the neck of the sac, is too general; it is also opposed by Diday (*b*).

1135. According to the degree of disproportion between the containing and contained parts of the rupture, is the severity of the symptoms thereon depending. Therefore either merely the communication between the rupture and the cavity of the belly is stopped, (*Incarceration; Incarceratio Herniæ*, Lat.; *Einsperrung*, Germ.,) or the protruded parts are at the same time so compressed, that the circulation of the blood and other juices is prevented (*Strangulation; Strangulatio Herniæ*, Lat.; *Einklemmung*, Germ.) In the latter case, the symptoms are dependent on the arrested passage of the intestinal matter, and on inflammation; they become very active, on which account, this kind of strangulation is called *inflammatory* or *acute*. In the former case, at least at the onset, the symptoms depend only on the arrested passage of the stools, they are little severe, and may continue longer, wherefore this kind of strangulation is distinguished as *chronic;* but it runs earlier or later into inflammatory strangulation, if the disproportion proceed to the above-mentioned extent. It is usually connected with *long-continued overloading* of the intestine, lying in the rupture, with stools, or with spasmodic affection of the walls of the belly and intestines, in consequence of spasmodic, flatulent or bilious colic, by which the intestines are immovably retained in the rupture (*Spasmodic Incarceration.*)

Opinions are very various as to the nature of strangulation and the classification thereon grounded. Many assume that strangulation is always, as regards its nature, the same, that is, always *inflammatory*, and that no actual difference in its form occurs, but that it is only acute or chronic according to the degree and severity of the strangulation and the circumstances attending it (Scarpa, Lawrence, Travers, Boyer Von Walther, Jaëger, and others.) Some take in its widest acceptation the division, proposed by Richter into inflammatory, spasmodic, and that caused by collection of stools, (Langenbeck, Wilhelm, Blasius, and others,) and differ only in their description of the symptoms, as they hold them, some as consequent on contraction of the abdominal muscles, especially of the front wall of the inguinal canal, (Langenbeck,) some as a consequence of the contraction of the internal muscular inguinal ring, (A. Cooper,) and some as resulting from the spasmodic motion and contraction of the tendinous parts, arising from every trifling irritation (Wilhelm.) Rust assumes, in reference to the seat of strangulation, a division *active* and *passive*, according as the parts forming the opening of the rupture contract, and grasp the protruded parts, or according

---

(*a*) Breidenbach, Ueber Einklemmung durch Zerreisung des Bruchsaches; in Heidelberg klinischen Annalen, vol. ii. pt. 1.

(*b*) Gazette Medicale de Paris. 1841. No. 19.

to their morbid condition, and he assumes according to the causal relations of the strangulation, an inflammatory, spasmodic, organic (from the stricture of the hernial sac, loops of *omentum* or intestine, adhesions, and the like) and fæculent division. SINOGOVITZ (*a*) considers strangulation as varying only in degree, according as by it the communication is completely cut off or only rendered difficult to a greater or less extent; all the other statements applied to strangulation were only from sympathy of the alimentary canal, namely, from local hindrance of the circulation of the blood and contents of the intestine. This view was already taken by SEILER, and arranged according to this division under imperfect and perfect strangulation and incarceration, and also according to the symptoms, without inflammation, with collection of excrement, with spasm, and with inflammation (*b*).

From these various opinions may be observed, that the views above mentioned differ from each other chiefly in relation to spasmodic strangulation; that in the manner presumed by many, an active spontaneous contraction of the opening into the belly should take place, is just as untenable as the notion of an active strangulation in general; since a spontaneous contraction of the abdominal ring cannot be admitted, external or oblique inguinal rupture, perhaps, excepted, where the muscular fibres forming the internal ring may, as A. COOPER himself admits, contract. The spasmodic affection in ruptures must be sought not in the containing parts, but in the contents of the rupture; and as the inflammation, although not the cause, is usually a consequence of the strangulation, so must the spasm be considered as an important symptom accompanying the strangulation, by getting rid of which we may hope to be enabled to fulfil the principal indication, namely, to return the protruded intestine or to diminish the relatively too great bulk of the protruded parts. (SEILER.)

[The common and indiscriminate use of the terms strangulation and incarceration is very incorrect, for many ruptures are incarcerated which are not strangulated. An *incarcerated* rupture properly speaking is that kind of the disease, in which the protruded *omentum* or intestine, from some cause or other, cannot return or be returned into the belly, but does not produce any symptoms of disturbed intestinal functions. This is of very common occurrence, particularly in old and large ruptures, in which the only inconvenience is the bulkiness of the swelling. A *strangulated* rupture is on the contrary a most serious and quickly fatal disease. The protruded *omentum* sometimes tying down or compressing between itself and the hind wall of the belly, a portion or portions of the intestines still within the cavity of the belly, so as to prevent the passage of their contents, and thus causing vomiting and constipation; or a piece of intestine which has descended into the sac, is so girt by its neck, that the contents cannot pass through it, and even its mortification may ensue by the tightness of the neck of the sac preventing the flow of blood through it. These observations prove the marked distinction between incarceration and strangulation. It must, however, be remembered that every strangulated rupture is incarcerated till the stricture be removed, and it be rendered returnable; but the relief of the stricture does not necessarily get rid of the incarceration, as there may be other causes, as adhesions or size of the protruded part, which prevent its return. Therefore every strangulated rupture is incarcerated, and a rupture may be strangulated and incarcerated, or it may be simply incarcerated or incapable of return without producing any symptoms.—J. F. S.]

1136. The symptoms of *acute strangulation* which usually set in after the sudden protrusion of a considerable quantity of intestine, or in a suddenly produced rupture after violent exertion and the like, or in those which have been long kept up by a truss, are, more severe pain in the hernial swelling and a sensation, as if a cord were tied round the belly; the rupture is tense, elastic, and cannot be returned; belchings and vomiting of the contents of the stomach, subsequently, of bile, and at last, of fluid stool and part of the clysters; the vomiting becomes more or less frequent, either of itself, or after the use of every, even of the mildest drink; the pulse, at first, quick and hard, subsequently becomes small and contracted; the belly is tense and tender, as is also the hernial swelling, and the skin covering it is frequently reddened; from the first there is obstinate costiveness, but when there are excrements in the large intestines, they can be

(*a*) Anleitung zu einer zweckmässigen Manual-hülfe bei eingeklemmten Leisten und Schenkel-brüchen. Danzig, 1830.

(*b*) RUST's Handb. der Chirurgie,—Art., *Hernia*.

emptied by clysters (1). In small ruptures which contain only one wall of the intestine, (LITTRE's (*a*) or *lateral rupture*,) the costiveness may be deficient or imperfect. If no assistance be afforded, the uneasiness, anxiety, tension, and painfulness of the belly and of the rupture increase, the vomiting becomes more frequent and painful, the body is covered with sweat, the pulse, quick, small, and thready, becomes irregular, the patient's countenance sinks in. Exacerbations and remissions of these symptoms, however, present themselves, and deceive both the patient and the practitioner.

[(1) Although costiveness is generally one of the symptoms of strangulation, it is by no means uncommon for the bowels to be relieved, and not unsparingly, although the strangulated bowel be impervious. This depends on the part of the intestinal canal strangulated; and the quantity of stool remaining in it below the protruded part.

I have on more than one occasion heard Surgeons of eminence speak of dilatation of a strangulated rupture on coughing, which I must confess I think impossible, if the rupture be more than incarcerated. LUKE, however, as will be hereafter shown (p.47,) when he describes the mode of ascertaining the seat of stricture, in reference to the operation for its division external to the sac, has explained that this dilatation is not of the part strangulated, but of that part of the rupture immediately above the seat of stricture, whilst that below remains unaltered. Such dilatation may happen when the seat of the stricture is at a distance below the mouth of the sac, but where the mouth itself is strictured, it cannot be possible.—J. F. S.

ASTLEY COOPER observes, that " when more than one irreducible *hernia* exists in the same person, it is sometimes difficult to determine which it is that requires operation ;" and he mentions the case of a woman, in which there was a rupture in each groin and another at the navel. Her symptoms not being urgent, the operation was deferred, and she died on the same evening. On *examination*, " the tumour in the right groin was found to be an enlarged and inflamed absorbent gland, lying over an empty hernial sac. In the left groin was a portion of inflamed intestine, and at the navel was an irreducible omental *hernia*, which had suppurated, and contained about a table-spoonful of matter." (p. 36–7.)]

1137. In a slighter degree of inflammation, and when it is long confined merely to the seat of strangulation, the symptoms are less violent and come on more slowly. The pain in the belly is not severe, but rather forcing, the belly remains soft, and not painful, the vomiting recurs at longer periods, and with less violence, the pulse is little or not at all altered. The symptoms first become more severe on the farther extension and increase of the inflammation.

1138. The *incarceration* from overloading the intestines lying in the rupture, or from collection of stools, occurs mostly in old and large ruptures, where the mouth of the rupture is wide and has lost its elasticity, after the patient has for some days felt unusual weight and dragging in the rupture, after using food difficult of digestion and flatulent; the rupture is little or not at all painful, not very tense, weighty, and doughy to the feel, and requires greater pressure in attempting its reduction; the belly is indeed full and swelled up, but not painful; if pain come on, it intermits; then follow belchings, vomiting, and costiveness. This incarceration, if it cannot be got rid of by proper treatment, may continue a long time before the symptoms become urgent, but earlier or later inflammation accompanies them.

1139. If there be with this incarceration, spasmodic symptoms, or if they occur in consequence of chilling, (especially in the feet,) or if spasmodic colic exist in sensitive persons, hypochondriacal or hysterical women, and after ailments which produce spasmodic, flatulent, or bilious

---

(*a*) LITTRE; in Mémoires de l'Académie des Sciences. 1700. RIECKE, C. F., Ueber Darm-Anhangsbrüche (*Herniæ Littericæ*) mit Bemerkungen über Kothfisteln u. widernatürlichen After. Berlin, 1841 ; with one copper plate.

colic, the symptoms come on more quickly, the rupture although tense is little or not painful, often changes its form, becomes larger, and again smaller; the pain shifts its place, subsides and returns; the evacuation of the bowels ceases; the patient generally does not vomit often, only after some drinks, whilst others he retains; the pulse is small, contracted, and irregular; the urine generally pale; the respiration difficult; the symptoms often quickly attain a great height, but again subside. Inflammation supervenes earlier or later upon the symptoms above mentioned, and it is therefore necessary to be very careful not to be deceived by the symptoms of slight inflammation, and to consider it as consequent on spasmodic affection.

1140. If the strangulation be not relieved, sloughing of the confined part is to be feared, and so much the more as the strangulation and inflammation are severe. The parts enclosed in the rupture are often gangrenous, without the external parts presenting any such change. But usually on the occurrence of gangrene the swelling loses its elasticity and painfulness, the skin becomes bluish-black at several places, emphysematous, and the *epidermis* separates; the painfulness of the belly and the vomiting cease; the powers sink; the pulse becomes small and irregular; cold sweats cover the limbs and face of the patient; the features are altered; the ideas become confused; the swelling bursts and discharges very offensive stool. Most commonly gangrene is the forerunner of death, the patient, however, may under these circumstances recover, the sloughy part of the intestine separates, and its remaining extremities adhering to the *peritoneum*, form an *artificial anus*.

1141. If the *omentum* alone be strangulated, the symptoms are generally not so severe, because it can more easily bear compression in proportion, as its structure is not already changed. The inflammation, however, spreads from the constricted part to the other intestines. Although the relief of the bowels be not suppressed, yet belching and vomiting occur. The constricted *omentum* may pass into suppuration and gangrene (1). Suppuration is an uncommon result; an abscess may form above the constricted part which may empty itself into the belly. Sloughing often occurs without any great effect upon the general condition of the patient; the sloughy part separates, and the remaining part adheres to the opening.

[(1) Key (*a*) makes a very important remark in reference to strangulated omental rupture, which, however, I do not remember to have observed; he says:—"When from the nature of the symptoms the case appears to be merely an omental *hernia*, the operation must not be hastily proposed, for it is not easy to distinguish between inflammation of *omentum* which has been irreducible, and strangulation; for the inflamed state of the *omentum* without strangulation, the operation will afford no relief; on the contrary, it will aggravate the inflammation. It is highly advisable, therefore, to try the effects of active general depletion, and the application of leeches to the part, under which treatment the symptoms will often disappear. The result of operations on omental *hernia*, which have been attended by acute symptoms, as great tenderness of the part, continued sickness, tense and tender belly, has been such as to induce me to try every means of allaying the inflammatory action before resorting to the operation. The operation, in the cases that have come under my notice, has not suspended the symptoms, as it generally does in enterocele, but the patient has sunk within a few hours from the effects of the inflammation." (p. 36, *note*.)]

1142. The *treatment* of ruptures differs according to the different circumstances under which they are met with, namely, *reducible* or *irreducible*, *strangulated* or *gangrenous*.

1143. In *reducible ruptures* the indication is to reduce the protruded

---

(*a*) A. Cooper, above cited.

parts and to prevent their reprotrusion. This treatment is either *palliative* by wearing a truss, or *radical*, by the organic closing of the hernial opening.

1144. The *reduction of a rupture* (*Taxis*, *Repositio Herniæ*, Lat.; *Zurückbringung eines Bruches*, Germ.; *Repoussement de la Hernie*, Fr.) is best effected early in the morning, when the bowels are empty, and the person is in a position, in which the walls of the belly are as much as possible relaxed, and the place of the rupture is most raised; therefore on the back, with the rump raised, the knees drawn up, and the body inclined towards the side on which the rupture is. Previous emptying of the urinary bladder, and of the large intestines with a clyster or purge will facilitate the *taxis*. The manœuvre of the reduction itself consists in a sufficiently moderate pressure upon the whole swelling, according to the direction in which it has been protruded; or in the greater size and more oblong form of the hernial swelling, the fingers of the right hand are to be applied from the bottom around the swelling, the thumb and the other fingers of the left hand upon the two sides of the abdominal opening, and then it is to be attempted with the right hand to return the rupture according to its direction, whilst with the fingers of the other hand the parts returned are to be kept up. Often the *taxis* operates very easily, but often a part of the contents of the intestine must be first returned by a moderate pressure on the rupture. During the reduction the patient must avoid all contraction of the walls of the belly. In proper positions of the body, small ruptures often return of themselves.

[In attempting the reduction of a rupture by the *taxis*, it is always advisable to make gentle and steady pressure over the whole swelling for a few minutes, in order to empty into the belly any fluid contained in the sac, so that the protruded gut or *omentum* may be more effectually acted on by the fingers. The same pressure should also be employed with the hope of emptying some part or all the contents of the intestine, if any be down, by which its bulk being reduced, its return is considerably facilitated by the special pressure of the *taxis*. The fluid of the sac can generally be emptied, so that a very considerable reduction in the size of the swelling is effected, and the Surgeon often fancies he has returned a large portion of the protruded gut or *omentum*, when in reality not the least part of it has moved, as the exposure of the bowel by the operation proves. The return of the contents of the gut depends on their fluid character, and on the tightness of the stricture, and is far less frequently effected than that of the fluid of the sac.

Violence in the use of the *taxis* is highly objectionable; instances have occurred in which the gut has been burst by it: one such case I have witnessed, and have known of others. Even when the injury is not so fatal, the violent squeezing to which a rupture is very commonly subjected damages its contents, especially if intestine be down, by the bruising which results therefrom, and renders the success of a subsequent operation very doubtful. I have seen several instances in which the gut presented large patches of *ecchymosis* which could have arisen from no other cause; and I believe that to this rough handling is mainly attributable the unsuccessful results of operations when the rupture has been long strangulated, and the *taxis* has been repeatedly employed with an unsparing hand. The reduction should therefore be attempted only with great caution, and with moderate and careful pressure. If after the warm bath and bleeding, the rupture cannot be reduced by the *taxis* applied not beyond half an hour, I think it is best to proceed at once to the operation, as least dangerous to the patient. Occasionally it will happen that, after the Surgeon's efforts have failed, the patient himself will succeed in returning the rupture; or he may suddenly become very faint, and the bowel return spontaneously, in consequence of the relaxation of the parts permitting the peristaltic action of the intestines within the belly, or some accidental movement of the body, acting upon the portion within the stricture, so as just to shift its place, which effected, the return soon follows, even without the application of ice, or any other remedy to empty the vessels of the part.

It sometimes happens in the efforts made either by the patient himself or by the Surgeon, to reduce a rupture, that instead of its contents merely being reduced, as in ordinary cases, the whole tumour, sac, bowel, and all, is thrust up into the belly, and the reduction seemingly effected, but the symptoms of strangulation still continue, and the patient dies; nor is it till after examination of the body that the cause of the mischief is found out. To this unhappy mode of returning a rupture the French Surgeons have given the names *Réduction en bloc*, or *Réduction en masse.* It appears to have been first noticed by Le Dran (*a*), in a man with femoral rupture, which had been reduced twenty-four hours after its strangulation. The symptoms, however, did not cease, but continued for a week, at the end of which Le Dran saw him; but he was too nearly gone to admit of operation, and died the same evening. The Surgeon first in attendance said, "that at the time of the reduction, he did not hear that noise the intestine generally makes when it enters into the belly; and that the parts composing the rupture passed in a heap under the ligament, like a tennis ball. * * * Upon opening the body we found the hernial sac in the belly, about three inches in depth, and eight in circumference, and within it was contained half an ell of the *intestinum jejunum.*" (p. 14) Le Dran directs in such case that "a cut should be made where the rupture was, and that the ring should be dilated or the ligament divided, in order to draw the sac back with the fingers, or a pair of forceps. The sac should then be cut open, its entrance dilated, and the intestine reduced. The sac cannot be far distant, since it is a part of the *peritoneum* that lines the inside of the *pelvis.*" (p. 21.) De la Faye (*b*) and Arnaud (*c*) confirmed Le Dran's observation by their own experience; but the fact was disputed by Louis (*d*) on account of the presumed connexion of the sac with the surrounding parts, and its large size rendering its return beneath the crural arch very difficult. Richter (*e*), however, defended the statement of Le Dran. Another case occurred to Scarpa (*f*), in a boy of thirteen, in whom the symptoms of strangulation continued after the presumed reduction of the rupture; "in fact, in the dead body of this boy there was not externally the smallest appearance of tumour in the inguinal region; but on opening the *abdomen*, it was immediately discovered that the intestine, still strangulated by the neck of the hernial sac, had been pushed up along with the sac beyond the ring, where it was seen rolled up between the aponeurotic *parietes* of the *abdomen* and the great sac of the *peritoneum.*" (p. 49; Engl. Edit. p. 143.) Sabatier, Dupuytren, and Sanson, have also had cases of this kind, and Dupuytren has had not less than six of them (*g*).

It is a very curious circumstance, that although these cases of reduced ruptures in mass, do not seem to have been very rare in France, yet till very lately they have been scarcely ever noticed in this country. Lawrence says:—"I have never seen a rupture reduced in a mass in this manner in the living body; nor have I seen any example of such a reduction in pathological collections." (p. 94.) And Key (*h*) observes:—"I have never known this to take place when the *hernia* has been reduced by the taxis." (p. 121.) Sir Charles Bell mentions (*i*) a case of this kind, in which "a tumour was discovered quite within the muscular walls of the *abdomen*, which proved to be the strangulated intestine within the peritoneal sac: so that the Surgeon had reduced the sac and the intestine within it: and the stricture which produced the strangulation being in the mouth of the sac, there was no relief, and the patient died." (p. 926.)

In the Museum of the Royal College of Surgeons there is an example of an inguinal rupture reduced in mass, and pushed between the abdominal and iliac muscles, and the *peritoneum*, part lying below the crural arch and extending outwards nearly as far as the external iliac vessels. It forms a considerable swelling inwards towards the cavity of the belly, but is not perceptible externally. The rupture was an old one, and the patient having worn a truss, was not inconvenienced by it, nor ever had difficulty in returning it, till it became strangulated.

Another case occurred in consultation to my friends Green and Callaway, in the year 1836, and to them I am indebted for the following particulars. The patient, it appeared, had several years before, whilst in Spain, had symptoms of strangulation and a swelling in the *scrotum*, which having been pushed up completely by a Spanish Surgeon, after a time the symptoms subsided; and he was not further inconvenienced until the attack now to be mentioned. On this occasion there was a swelling on the left side of the *scrotum*, irreducible but transparent, and accompanied with symptoms of strangulation. No relief was obtained by medicine, and it was determined to perform

an exploratory operation. A cut was made into the swelling, the fluid evacuated, and the finger being introduced, readily passed in and turned freely about, and the intestines were felt, as it seemed, in the belly, and free from strangulation. The symptoms, however, continued, and the patient died four days after their onset. On *examination* it was found that the cavity, opened in the *scrotum*, did not, as supposed, permit the finger to pass directly into the general cavity of the *peritoneum*, but into a large sac lying between the iliac *fascia* and the *m. iliacus*, in which were contained intestines, and these were strangulated in a small aperture at the upper inner side of the sac, where was the communication with the cavity of the belly. The testicle lay behind the scrotal sac, just at the external abdominal ring. **Green** supposes that the rupture was originally congenital, and that when the patient was in Spain, the Surgeon had violently thrust up the whole rupture and the testicle into the belly, the sac doubling on itself; but that the intestine had then partially or completely relieved itself, and that afterwards the sac had lengthened downwards, forming the swelling filled with fluid which existed in the *scrotum*, and had been cut into.

The next case recorded, is that under **Bransby Cooper**'s care in 1839, already mentioned, (*par.* 1117,) in which there were two sacs.

The attention of English Surgeons was certainly, however, scarcely drawn to the reduction in mass of a rupture, by the taxis, till **Luke**'s paper (*a*) was read before the Medico-Chirurgical Society, in the spring of 1843; and a perusal of the discussion thereon (*b*), clearly proves, that although it was attempted to show the subject had been previously well known, yet none of the speakers produced reference to any other than the few cases which I have already noticed, neither did any one allude to those of **Dupuytren** or **Sanson**. It must therefore be admitted, that **Luke** is fairly entitled to the credit of having brought the subject fairly before English Surgeons, for although he has also availed himself of the experience of the French, he mentions not less than five cases which had come under his own notice, three of which were after death, and two he had under treatment, and gives account of; one of which would not submit to an operation and died, whilst the other was operated on and recovered.

The possibility of returning a rupture in mass, which had been doubted or denied, was clearly proved by **Jules Cloquet** (*c*) in his experiments on the dead subject. He says:—"When the neck of the sac does not adhere very strongly to the aponeurotic opening, and the latter is also somewhat dilated, which is not uncommon, in pushing violently the rupture towards the cavity of the belly, the cellular adhesions of the neck, and of the aponeurotic ring lengthen and break; the two openings which were near, separate from each other; the former sinks, passing inwards, whilst the latter retains its place. Whilst the *taxis* is employed the cone above the neck of the sac on its abdominal side becomes very prominent and much lengthened, is no longer formed as in the former case, (where the neck of the sac adhered closely to the aponeurotic opening,) by the whole thickness of the abdominal wall, but merely by the *peritoneum* raised and detached from the muscles, by the sac which endeavours to get between those parts. The sac re-enters successively, and by little and little, through the aponeurotic ring as it dilates; and towards the end of the experiment it escapes suddenly, and gets behind this opening. It is then easily felt through the abdominal walls, by placing the finger on the spot which the rupture had occupied; it forms a large, hard, round, chestnut-like tumour deeply-seated above the ring. In this case the reduction is complete, the rupture has returned *en bloc*, and is situated between the abdominal *peritoneum* and the posterior surface of the aponeurotic ring. The ring contracts slightly, by its elasticity, as soon as the sac has entirely slipped over it, and to a certain point prevents the reappearance of the tumour externally. This reduction *en bloc* is sometimes followed by a slight rush, in consequence of the hasty passage of the bottom of the sac through the ring; but this rush never happens when the ring is very loose and wide. * * * When this last condition exists the tumour goes in and out with equal readiness. I have accomplished reduction in mass in about twenty-five instances, partly of ruptures either strangulated or otherwise irreducible, partly of empty hernial sacs. It is effected most easily in internal (direct) inguinal, then in crural, and lastly in external (oblique) inguinal ruptures. I have never succeeded in umbilical ruptures in adults. When the sac is of considerable size, when it adheres closely to the surrounding parts, when the aponeurotic opening is small, and in the form of a canal, circumstances which are frequently met with in external (oblique) inguinal ruptures, this kind of reduction is almost impossible, unless great force is employed. * * * The replacement in mass of a

---

(*a*) Cases of Strangulated Hernia reduced *en masse*, with observations; in Med.-chirurg. Trans., vol. xxvi. p. 159.

(*b*) Lancet, 1842–3, vol. ii. p. 242–45.

(*c*) Recherches sur les Causes, &c. above cited.

rupture strictured by the neck of the sac, takes place most easily when the aponeurotic ring is of large size and short; when the sac and its neck are loosely connected to the surrounding parts; and when the protruded *viscera* adhere together, and to the sac, so that reduction in the usual way is impracticable. In a case of internal (direct) inguinal and in another of crural rupture, I found that the tumour could only be returned in a mass, although the neck of the sac was not narrow, in consequence of close adhesions between the protruded parts and their peritoneal covering." (p. 113-15.)

The following are some of the more important of LUKE's pertinent observations (a) in reference to the existence of a rupture reduced in mass, when without any tumour symptoms of strangulation are present:—"The too exclusive reliance upon the absence of tumour as a sign of the non-existence of a *hernia*, may, in certain cases, be highly dangerous. In suspected cases, more security will be derived from the institution of inquiries concerning the *previous existence* of a tumour in the part, and of its conditions when ascertained to have existed, such as its hardness, or the reverse, its freedom from pain, and also the amount of, and the manner of applying the force used for its reduction. By such inquiries, not only may the dependence of the symptoms of intestinal obstruction upon hernial strangulation be determined, but also the presumption of a reduction *en masse* may be raised or removed. Should such a presumption be raised, the Surgeon will then be prepared to push his inquiries further, and to seek for indications to direct his *diagnosis*, which are not usually sought for in ordinary examinations. The mode of proceeding to render these indications available to our use, is twofold. That, however, will in prudence be first adopted which requires mere manual examination without incision, while the second should be had recourse to, provided the first tends to strengthen the presumption of a reduction *en masse* previously raised. * * * It is a circumstance worthy of remark, that the firmness of the adhesions of the parts in which it is imbedded, bears no proportion to the duration of the hernial protrusion, as might be, *à priori*, expected; for in all the cases (of reduction in mass) related, the *hernia* had been of some years' continuance, yet in each was reduced without the employment of much force.

"The presence of sac, even without hernial contents, causes an abnormal fulness in the part, easily ascertainable by examination. The absence of such fulness in a part, when *hernia* is known to have previously descended, necessarily leads to the conclusion that the sac upon which it depended has been displaced, and probably returned, together with the *hernia*. The sac in inguinal *hernia*, below the external ring, becomes united with the spermatic cord, whereby the latter is usually rendered indistinct and obscure. The absence of that indistinctness and obscurity implies the removal of the cause which previously produced them, and, therefore, that the sac has been displaced. The continuance of the indistinctness and obscurity leads to a directly contrary conclusion. When a *hernia* descends from the *abdomen*, the aperture through which it descends is always enlarged and dilated. This fact is ascertainable by the introduction of a finger, a circumstance which becomes available to the *diagnosis* in these cases. Should a large aperture be detected, a previous hernial descent may be inferred. Under ordinary circumstances of *hernia*, when the contents are reduced into the *abdomen*, the area of the aperture is occupied by the remaining sac, while its margins are rendered more or less obscure. If, then, a large aperture be found free and unobstructed, with its margins unobscured, there is raised not only a presumptive evidence of the previous protrusion of a *hernia* at the part, but also the further evidence of the displacement and probable return into the *abdomen* of the sac by which the *hernia* had been invested. We are led to a contrary conclusion by contrary circumstances. These, I believe, are the only indications useful to *diagnosis*, resulting from changes caused by the previous descent of a *hernia*, at or below the abdominal ring.

"Nor does the examination of the inguinal canal afford any available information, unless a tumour be discoverable in its course; a circumstance which, by the clearness of the evidence it affords, renders the *diagnosis* comparatively easy, and affirmatively conclusive, but constitutes a description of case not intended to be included in the scope of the present observations, which are directed exclusively to cases unattended by any external appearance of tumour.

"Yet, in conducting an examination of the *abdomen*, immediately above the seat of the internal ring, some corroborative evidence of a reduction *en masse* may sometimes be obtained. Thus it may be expected, that if such reduction has been effected, the inflammation of the hernial contents will cause a circumscribed pain in the seat which it occupies, while a fulness, or even the rounded form of the *hernia* deeply situated within the abdominal *parietes*, may possibly be cognizable upon a minute examination;

(a) Cases of Strangulated Hernia reduced *en masse*, with observations, in Med-Chir. Trans., vol. xxvi.

yet the absence both of circumscribed pain, and of fulness or rounded form, should not lead to a negative opinion; for, in the first case, neither pain nor fulness existed, yet subsequently a mass of strangulated intestine was discovered at the part. Their presence, however, may be taken as corroborative of an affirmative opinion, founded upon the manual examination previously instituted.

"If circumstances justify a suspicion of a reduction *en masse* in any case, they will also justify attempts to cause reprotrusion of the tumour, that, by bringing it into view, the obscurity of the *diagnosis* may be wholly removed. With this intention, as advised by Surgeons of authority in such matters, the patient should be placed in the erect posture, and be requested to cough forcibly, to strain, and to make exertion. This course of proceeding seems likely to be of use when the hernial tumour is either in the inguinal canal or at the internal ring; but if it be reduced within the *abdomen*, as in the cases related, beyond the situation of the ring, the probability of affecting its reprotrusion will be much diminished, and consequently an opinion of the non-existence of a reduction *en masse*, drawn from the non-appearance of a tumour, is to be cautiously avoided."

Although, after "the most rigid local manual examination, the indications afforded for our guidance are so obscurely marked," as to afford "a sufficient explanation why Surgeons, under these circumstances, are usually unwilling to have recourse to ulterior measures of examination, by submitting the patient to the certain pain and possible danger of an exploring operation, yet such unwillingness may prevent the adoption of the only means of preserving the patient's life. As the doubts and difficulties of such cases can be removed only by the light which an operation of exploration affords, it is the obvious duty of the Surgeon to make that unwillingness yield to the pressing emergencies of the occasion. * * * It should be remembered that an unsuccessful attempt is infinitely to be preferred to no attempt at all, and that passiveness on his part may be more destructive to life than any incisions which he may be required to make." (p. 175-79.)

With these observations of Luke I most fully concur, and more especially, because there appears to be pretty good grounds for finding the reduced rupture at a particular spot, as Dupuytren (*a*) observes:—"When the hernial tumour is reduced in mass it cannot move about in the belly, because it is formed, in part at least, by the *peritoneum*, which although movable, remains always in the region to which it belongs, and consequently retains the tumour. The rupture is then permanently behind the opening, by which it has returned and resting on its internal surface. Surrounded by the cellular tissue, which had previously united the *peritoneum* to the wall of the belly, and which has been displaced to receive it, the returned tumour is found, besides, to be covered with a second layer of *peritoneum*, which is actually that detached from the hind surface of the belly; so that to penetrate the hernial sac, by cutting through the abdominal wall, the *peritoneum* must be twice cut, and its cavity opened before reaching the cavity of the sac, unless the operation were performed like that for tying the external iliac artery, by raising and detaching the serous membrane. Dupuytren does not, however, advise either cutting through the *peritoneum* and opening the abdominal cavity, or turning off that membrane to get at the hernial sac. "There is fortunately," says he, "a more simple and less dangerous mode of treatment, which consists in seeking for and drawing down the rupture by the opening through which it had passed into the belly, being assured it will be found resting on the internal surface of that opening, where it can be laid hold of with the forceps, and drawn out, with or without cutting the edge of the ring. If the tumour be examined through the cavity of the *peritoneum*, it will be seen lodged in the iliac pit, a little more outwards in crural rupture, a little more inwards and deeper in inguinal rupture. It presents a narrow, tight opening, in which the two ends of the intestine are plunged, forming a loop in the cavity of the sac. It is at this point that the intestines are compressed, narrowed, shrunk, strangulated, and mortified, the upper end more frequently than the lower; the former bulges almost to bursting; the latter, shrunk, empty, and like the intestine of a child." (p. 592-94.)

"In conducting operations of exploration," observes Luke, "the indications which are to be sought for, are, for the most part, of a similar nature to those already mentioned, as useful in the manual examination. They are, however, more satisfactory and distinct, inasmuch as the parts to be examined are, by our incisions, brought immediately into view, and are not obscured by the interposition of superjacent structures. Thus by the perfect exposure of the external inguinal ring, * * * if the size of the ring be normal, a *hernia* has not descended through it; or if it be larger than the normal state, yet occupied by an empty sac, an evidence of the previous existence of a *hernia*, together with an evidence of the reduction of the *hernia* without the sac being also reduced, is established. But should the ring be found large and free from other obstructions than the cord, and if the

(*a*) Above cited.

cord be distinct and unobscured by the presence of a sac, and a void is found where fulness is to be expected from the previous history of the case, a strong presumptive evidence on the contrary side is established, that the *hernia*, together with its investing sac, is reduced.

In proceeding with the exploration, the inguinal canal is next laid open. * * * I hold a close observance of the condition of parts within the canal to be a matter of very great importance. It will be recollected that the ordinary oblique inguinal *hernia*, during its passage through the canal, lies anterior to the spermatic cord. The hernial sac, when left empty after the reduction of its contents, occupies the same relative situation, and consequently overlays and obscures the cord after the canal is laid open. If the reverse of this is found in a case where a hernial descent is known to have previously existed, and the cord is ascertained to be clearly and distinctly brought into view, throughout the whole extent of the canal we may justly conclude, that the distinctness and clearness with which the cord is seen are caused by the removal and consequent reduction of the hernial sac from over it, which reduction can be effected in no other direction than into the *abdomen*.

"The condensed cellular capsule (usually found) immediately investing the sac * * * has but little connexion with the sac, and will remain even when the sore has been reduced. * * * If found and ascertained to be empty, the circumstance is of a very conclusive character, and moreover will afford a direct clue to the situation of the *hernia*. A finger introduced through an opening made in such capsule, will be conducted towards or through the internal ring, beyond which it will be brought into contact with the hernial tumour itself, having in the introduction passed through the same channel by which the reduction was effected.

"The indications to be noticed at the internal ring are of a similar nature to those mentioned as being found at the external ring, and relate to the size of the aperture and the structures by which it is occupied.

"It will be observed that up to this period the proceedings of the exploration have been conducted without any danger of importance, and without any necessary disturbance to the *peritoneum*, yet information of the most conclusive kind may have been obtained, and such circumstances brought under notice as could fully justify the operation, even if manifold, more hazardous than it really is. * * *

"The operation may be conducted to a demonstrative conclusion, by ascertaining the existence or non-existence of a hernial tumour, without adding materially to the trifling danger already incurred. This is accomplished simply by the introduction of the finger through the internal ring, and by passing it from side to side. Should a hernial tumour be present, it will at once be recognised, and found lying externally to the general peritoneal membrane, although within the *parietes*, and presenting a rounded surface. Should a tumour be not present, the circumstance may be ascertained by observing the smooth surface of the *peritoneum*, and the continued adhesions which it maintains with the *parietes* immediately surrounding the ring. If doubt still exists, an enlargement of the internal ring, by division of the adjoining *transversalis fascia*, will afford a clearer exposition of parts, and a more decisive evidence for either an affirmative or a negative conclusion; and thus an exploration may be conducted to its termination without the necessity of any peritoneal section.

"When the doubts have been resolved in the affirmative, by the discovery of a hernial tumour, the tumour may be brought into the inguinal canal, so as to occupy its former situation before reduction, by enlarging the ring to the requisite extent for its passage. It may afterwards be opened, and its contents dealt with according to their condition, as under the ordinary circumstances of common operations. * * *

"The sac should, in all circumstances be opened, and its neck freely divided, so as not to leave any impediment to reduction of its contents into the general peritoneal cavity. It should be recollected also, that the adhesion of the sac to the surrounding parts has been severed, and that consequently, the sac will be liable to be again reduced during the reduction of the contents into the *abdomen* unless caution be used for its prevention. The danger of this occurrence may be always obviated by the introduction of the finger through the neck of the sac, after the contents have been reduced, for thus the fact of their perfect liberation may be readily ascertained." (p. 180-85.)]

1145. If the rupture be completely reduced, which can be determined by introducing the finger into the abdominal ring, its re-descent is to be prevented by continual suitable pressure, which is to be made by proper bandages, *Trusses*, (*Bracheria*, Lat.; *Bruchband*, Germ.; *Brayer*, Fr.,) upon the hernial opening.

Upon the subject of Trusses, see

Camper; in Mémoires de l'Académie de Chirurgie, vol. v.

Cooper Astley, above cited, p. 21.

Cloquet, Art. *Brayer*; in Dict. de Médecine, vol. v. 1834.

1146. *Trusses* are either *elastic* or *inelastic*. The latter consist of a strap of fustian, leather, or the like, and of a *pad*. When applied, they may not yield to the movements of the coverings of the belly, may therefore be very easily displaced, the intestines slip from them, and if this be prevented by drawing tight, painful pressure is produced. Upon these grounds the inelastic trusses are to be altogether rejected.

1147. *Elastic trusses* consist of, *first*, a *spring*; *second*, a *pad*; and, *third*, of a circular *strap*. The *spring* is a narrow flat piece of well-hardened steel, which bends in a semicircle around the diseased side. A plate of steel is attached in front to the spring and its inner surface padded with wool or horse-hair, so that it may form a soft but regular arching, this part is called the *pad*. At the hinder end of the spring is a circular strap, which passes round the other side of the body, and is fastened to a button on the outer surface of the pad. The whole truss is to be covered with soft leather and lined on the inside, so that it may not make any troublesome pressure.

1148. The truss must be made with great care in each of its parts, and be fitted to every individual case. The *strength of the spring* must correspond to the resistance which it has to afford, and fit well to that side of the body on which it is applied. The *pad* must have a *size* corresponding to the bulk of the rupture, and the *angle* at which it stands from the spring correspond to the surface on which it is applied, which it has been also attempted to effect by a *movable pad*, in order to suit it to every case. The *pad* must not be *too soft* nor *too hard*, and its convexity must be such that it may be regularly over the whole hernial opening; pads of hard wood, ivory, or filled with air, (Cresson and Sanson,) are less certain and suitable. If the circular strap alone be insufficient to keep the truss in its proper place, we must endeavour to prevent its displacement by a second strap, carried between the thighs.

In order that the truss may be sufficiently firm, it is necessary in every case to take the size, by means of a bandage carried round the body from the seat of the rupture and in the direction on which the truss is to lie; or for the same purpose, a double piece of flexible wire may be used, with which the necessary curve can be given; about an inch must be added to the size on account of the covering of the strap.

1149. The truss is to be applied after the proper use of the *taxis* for the reduction, whilst with the fingers the intestines are kept up, till the pad be properly applied on the hernial opening, and the strap be fastened. The patient should then cough, and stand up, to determine that the truss is not put on too tightly and that the parts are well kept up. The Surgeon should always apply the truss the first time; subsequently the patient may do it himself, but it should be whilst lying on his back and early in the morning; he should also have several trusses for the purpose of change. The part on which the truss rests should be frequently washed with brandy, till the teguments are accustomed to its pressure. If excoriations occur, the parts should be washed frequently with lead wash, whitelead should be strewed over it, and a thick piece of linen applied beneath the truss.

1150. Various diseases in the neighbourhood of the opening upon which the pressure must be made, and an imperfectly reduced rupture may prevent the use of the truss. Large ruptures are extremely difficult to reduce, and often new ruptures occur afterwards in other parts. In children the use of an elastic truss is not only acompanied with no injury, as many suppose, but it is to be preferred to the use of an inelastic one.

1151. When an adhesion prevents the return of a rupture to such extent that part of it remains external, a truss with a hollow pad may be used; but in very large irreducible ruptures a suspendor sufficient to enclose it, should be used to prevent the further protrusion of the intestine. In these ruptures the gradual return is effected by long-continued lying on the back, by slender diet, purging, frequently cold applications over the rupture, and by daily repeated attempts at reduction, which has occurred to me in several cases of very large and adherent ruptures. When in large ruptures the walls of the belly are so contracted that the parts in the rupture have scarcely any room in the belly, the same treatment is indicated. Frequently in such cases, after the reduction and the application of a truss, anxiety, oppression, pain, small pulse, and so on occur, and it becomes necessary to remove the truss, after which the symptoms, as I have observed, subside.

1152. When the intestines are properly kept up by the truss, the hernial sac gradually contracts, and at the same time a slow inflammation arises, consequent on the pressure of the truss, by which perfect adhesion of the neck of the hernial sac takes place, and thus a *radical* cure is effected. This commonly happens in children, frequently in adults, but never in old persons. On account of this gradual narrowing of the neck of the hernial sac, under the continued use of the truss, the latter may not be again removed if it be not believed certain that the radical cure is effected; because otherwise, in repeated protrusions of the intestines, strangulation may also arise from the contracted neck of the sac. Whilst the patient wears the truss he must avoid all violent exertion.

[CLOQUET considers that a hernial sac may be returned spontaneously into the belly in four different ways. *First*, by the contractility it possesses in common with other tissues, having a constant tendency to retract the sac upon itself, after its distension, and which is, in some cases, sufficient to produce a gentle and gradual return. "The sac then takes a retrograde movement to that of its formation; the *peritoneum* passes from the ring towards the parts it had left, that portion of this membrane, which had been drawn towards the ring without passing through it, pulls the neck in every direction, which expands, turns out in some degree, disappears, and at last is effaced; the sac unfolds, and again covers the wall of the belly, near the aponeurotic opening. The neck of the sac, which was last formed, disappears first, whilst its bottom disappears last, and with great difficulty, so that the reduction is often incomplete." (p. 74.) When a rupture has been thus reduced, the remains of the neck are sometimes observed at a little distance from the ring, in the shape of irregular *stygmata*, whitish, and more or less opaque. The *peritoneum*, which formed the sac, is restored to the abdominal wall. * * * Sometimes these sacs are so completely effaced, that no trace of them can be found in the *peritoneum* covering the ring by which they had escaped. The only indication of a rupture having existed at this spot, is a cellular, whitish, empty pouch, arising from the aponeurotic ring." (p. 76.) *Second*, "by the closing, the gentle and insensible contraction of the cellular tissue external to the sac. The other tunics may concur also; but their action appears more weak, and less demonstrable. * * * In this case the *peritoneum* presents at the top of the ring irregular, prominent folds, analogous to those of the mucous membrane of the stomach during the contraction of its muscular coat." (pp. 78, 9.) *Third*, by the displacement of the *peritoneum* from the abdominal wall from various causes, as in two cases of direct inguinal rupture, in which, in consequence of retention of urine, the *peritoneum* covering the bladder was raised nearly to the navel—by enlargement of the womb by pregnancy, or any other cause—by adhesion of the *omentum*, or intestine to the hernial sac—by a large quantity of fat collecting between the *peritoneum* and wall of the belly—or by the dragging of another sac which has formed in the neighbourhood of the former. *Fourth*, by the contraction of the cremaster muscle; "the two fleshy bundles of which act upon the sac pretty much as the two bellies of the digastric muscle effect the direct elevation of that bone." (p. 83.)]

1153. The *radical cure* of reducible ruptures (especially inguinal ruptures) was attempted in ancient times in very different and in part cruel and barbarous ways, which had only their corresponding excuse in the ignorance of, or in the bad construction of trusses. Even later modes of treatment have found little favour, on account of the danger therewith connected, and because of the more perfect construction of trusses; and only of late have these objects again attracted more attention, and less dangerous methods of treatment have been proposed. All the modes of treatment in reference to the radical cure have for their object the organic closing of the neck of the hernial sac, or of the abdominal ring, or to effect both at once, which has been attempted by a sufficient degree of *adhesive* or *suppurative inflammation*, and thereby causing *adhesion;* or by a *plug of skin healed into the abdominal ring*. These may be collected together under the following heads: *first*, Increased pressure whilst lying constantly on the back, with, or without the simultaneous application of irritating and contracting remedies; *second*, Caustics and the actual cautery; *third*, Ligature of the sac, with or without cutting it off; *fourth*, Introduction of foreign bodies into the hernial sac; *fifth*, Healing-in of a detached portion of skin, or of a portion of infolded skin, into the abdominal ring.

1154. Increased pressure, whilst the patient lies constantly on his back, heretofore employed by FABR. HILDANUS, BLEGNY, WINSLOW and others, has of late been recommended by means of a common pad, (RICHTER and others,) with a conical linen pad, the point of which is inserted into the abdominal ring by means of an elastic truss; the supine posture is to be continued at least four weeks, till superficial ulceration take place, which should be dressed with lead cerate, and the truss still applied tightly for some time (LANGENBECK) (*a*); at the same time a sponge dipped in turpentine, or a blister, is to be put on beneath the pad (BOYER); with a pad of which the power can be increased by means of a compressing screw, with a pressure apparatus moistened with alum wash (RAVIN) (*b*); or with a pad filled with contracting herbs, and subcarbonate of ammonia (BEAUMONT) (*c*).

Various irritating and astringent remedies have been mentioned which have been employed in blisters, bags, pads and as washes; to wit, bark, tormentilla, gall nuts, oak bark, rhatany, alum, turpentine, ætherial oils, naphtha, washing with cold water, iron bullets, cold river bathing, and so on. JALADE LAFOND (*d*) employs a pad with a reservoir for holding caustic.

1155. The application of the *actual cautery*, derived from the Alex-

---

(*a*) Abhandlung von den Leisten und Schenkelbrüchen, p. 121.

(*b*) Essai sur la Théorie des Hernies et de leur étranglement, et de leur cure radicale. Paris, 1822.

(*c*) Notice sur les Hernies et une nouvelle manière de les guérir radicalement. Paris, 1827.

(*d*) Remarques nouvelles sur la cure radicale des Hernies simples sans opération sanglante. Second Edition. Paris, 1841.

andrian school and first described by Paulus Ægineta, and of *caustic* (recommended from early times, from Avicenna up to Kern) closes the hernial opening by destroying the skin and hernial sac, and forming a hard scar connected with the bone. After the rupture has been returned, and the cord drawn aside, the cautery is to be kept so firmly upon the abdominal ring, that it burn deeply through the skin and hernial sac down to the bone. In the same way caustics are to be applied, viz., caustic potash, arsenic or sublimate with opium, lime, sulphuric acid, one part of caustic potash, two of gum-arabic, and some water (Kern.) The cautery as well as the caustics have also been applied upon the hernial sac laid bare by incision (Franco, Monro.)

1156. *Tying up the hernial sac* with the *ligature* (*ligatura sacci herniosi*, Lat.; *Zusammenschnürung des Bruchsackes*, Germ.) and *stitching* (*sutura*, Lat.; *Naht*, Germ.) are performed in different ways: *first*, after the already directed reduction, encompassing the sac with a needle and tying together both it and the spermatic cord with a ligature; *second*, after previously laying bare the sac by an incision, encompassing the hernial sac and the spermatic cord with a needle, and introducing a golden thread which can be so drawn as to close the hernial sac, but the spermatic cord is not to be compressed, (the *golden puncture*, *punctum aureum*) (Berard, Franco); *third*, tying the hernial sac and the spermatic cord, and cutting both off below the ligature, or first cutting off both and then tying them (the *rupture-cutter* of the middle ages); *fourth*, separation of the hernial sac from the surrounding parts, and then tying it with a leaden thread, (Paré,) or closing it with the glover's stitch, the royal stitch, (*sutura regia*,) (Nuck, Fabr. ab Aquapendente, Guy de Chauliac, and others,) or simple tying with a waxed treble or quadruple thread. (Le Dran, Freitag, Senff, Schmucker, Theden and others,) in modern times Langenbeck and Kern, the latter of whom, in omental rupture, tied the exposed *omentum* near the abdominal or femoral ring, so that the remaining part of the *omentum*, by uniting with the walls of the ring, closed it up; *fifth*, incision into the integument and hernial sac, and treating as after the operation for strangulated rupture, with simple lint dressing and light pressure with a spica bandage or truss, (Petit, Lieutaud, Leblanc,) or with simultaneous scarifications of the hernial sac, (Freitag, Mauchart, Richter,) or with the introduction of tents of lint (Dionis, Mery, Arnaud, Schreger, von Graëfe, von Walther and others.) Here also belongs the injection of red wine, recommended by Schreger, and the inflation of air into the hernial sac, the mouth of the sac being carefully closed with pressure.

1157. The *inhealing of a plug of skin*, to close the mouth of the sac, is effected in two ways:—1. According to Dzondi's proposal (*a*), to heal within the abdominal ring, purposely wounded a sufficiently large fold of skin, formed by an incision of the skin; Jameson (*b*) made, in a femoral rupture, a fold of skin two inches long, and an inch wide, thrust it into the femoral ring, and united the edges of the skin with stitches. 2. Gerdy's inhealing of the skin, ensheathed in the inguinal canal (*c*). After the patient is placed, as in the operation for strangulated rupture, a finger of the left hand, smeared with cerate, is to be placed somewhat

---

(*a*) Geschichte des klin. Institutes zu Halle. p. 117.

(*b*) The Lancet, vol. ii. 1829, p. 142.

(*c*) Bulletin de Therapie, 1835.—Fink, Ueber radicale Heilung der Brüche. Freiburg, 1837; with two copper-plates.

beneath the hernial opening on the *scrotum*, and then the *scrotum* in front of it is to be thrust along the spermatic cord as deeply as possible into the inguinal canal. In this blind sac the finger is to remain, and the skin is to be thrust as far as possible towards the outer wall of the inguinal canal. A curved needle, with two cutting edges, and with a handle, and its eye armed with a double thread, is then to be introduced, on the palmar surface of the forefinger, to the bottom of the ensheathing, and whilst the handle of the needle is depressed, the needle itself, its convex surface resting on the palmar surface of the finger, is to be thrust, whilst an assistant presses the external skin against its point, from behind, forwards through the front of the ensheathed part of the *scrotum*, and the front wall of the inguinal canal, so that the needle projects some lines above the inguinal ring. The one end of the thread is now to be drawn out, and given to an assistant, the left finger still remaining in the ensheathing. The needle, in the eye of which the other end of the thread remains, is now again to be passed upon the finger, at some lines' distance from the former stitch, thrust through externally, and the thread withdrawn from it. After the removal of the needle, the threads are to be divided, and a cylinder of plaster placed between them, upon which they are to be tied, and the ensheathed part of the *scrotum* is firmly retained in its place. If the entrance and canal of the rupture be much enlarged, two other stitches must be applied; but in general, one is sufficient. The sac formed by the ensheathed skin, is to be then pencilled with caustic *liquor ammoniæ*, to excite inflammation, the part operated on covered with a pad, spread with cerate, and covered with a compress, and the patient put to bed in such position, that the rump and the head are somewhat raised, and the thighs drawn up. In all cases phlegmon follows, which spreads over the whole extent of the stitches, and runs into suppuration, the *pus* discharges itself through the stitches, along the threads, which, at the same time, also act as guides to it. If the adhesion have taken place in from three to five days, the stitches may be removed. Towards the fifteenth or twentieth day, the suppuration ceases, the ensheathed skin forms a plug, which externally appears like a swelling, but gradually subsides. The patient must, for four weeks, observe the supine posture, and the treatment must be conducted according to the inflammatory symptoms which may come on. SIGNORONI (*a*) thrusts up the skin, like the finger of a glove, into the sac of the rupture, and fixes it by means of a female catheter, then pierces it with three long hare-lip needles, four lines apart from each other, and twists around each an ∞-shaped thread. The needles are left six or eight days. WÜTZER (*b*) retains the skin thrust up into the inguinal canal, by means of a cylinder, on the under part of which is fastened a plate which fits the outer surface of the inguinal canal. A needle is thrust through the upper part of the cylinder, outwards, and brought out by an opening of the external plate.

Here must also be mentioned GARENGEOT'S proposal, according to the experiment once made by PETIT, that strangulation existing, if the mouth of the sac were expanded with one wound, and the opened hernial sac thrust back into the belly, the radical cure followed; this treatment might also apply to the attainment of the radical cure, as well also as the reduction of the exposed sac according to HUMMEL and STEPHENS.

[(1) BRANSBY COOPER (*c*) has performed GERDY'S operation. The application of the caustic ammonia caused intense pain in the part, for a few hours after the operation,

(*a*) Bulletino Medic. de Bologna, 1836, Dec. FRORIEP'S neue Notizen, vol. ii. p. 272.

(*b*) Organon für die gesammte Heilkunde, vol. i pt. 1.

(*c*) Guy's Hospital Reports, Oct., 1840, p. 270–75.

but no pain in the belly. On the fourth day, suppuration having been freely established, the ligature was removed, but the pressure was continued. On the fifth day, there appeared a degree of fulness about the margin of the opening, as if a portion of the inverted skin had descended, but without any descent of the intestine, and the hardness and swelling about the inguinal canal still led to the reasonable hope that the operation would prove successful. After some days, as the tenderness diminished, greater pressure was made. On the twenty-fourth day, a weak truss was applied, and he continued in bed ten days longer, after which time however he would not be confined, but got up and walked about, and soon after left the hospital. But he had a slight return of the rupture.]

1158. The most modern practices which may be placed next the former, are those of BONNET, MAYOR, and BELMAS.

BONNET (*a*) employed the same treatment as for *varicocele*, introducing needles upon the hernial sac, and allowing them to remain. The rupture having been reduced, the *scrotum* is to be grasped with the left hand, as close as possible to the abdominal ring, and the spermatic cord brought into the circle formed by the thumb and forefinger of this hand; a pin, with a piece of cork on its head, is to be thrust, close to the suspensory ligament of the *penis*, from the point of the finger nearest it, from behind and above, forwards and downwards, through the integuments and the hernial sac. A second piece of cork is to be fixed on the projecting point, and brought near the first piece, so that the intermediate soft parts are easily compressed; and in order to keep the second piece of cork in its place, the point of the pin is bent down. The spermatic cord is to be placed between this pin and the tip of the thumb and forefinger of the left hand, and a second pin is then introduced six lines distant externally from the first pin, parallel to it, and fastened in the same way. If the spermatic cord have been divided by the pressure of the intestine, into its several parts, a third pin must be passed, six lines from the second, so that the other parts of the cord may be placed between the second and third pins. Usually, about the fourth day, pain and inflammation come on; but the pins are not to be removed till the inflammation has acquired a certain degree of intensity, and the hindmost piece of cork has excited ulceration of the skin, which occurs about the sixth, or even at the twelfth day. By this proceeding, not merely is the hernial sac, but also the abdominal ring closed, and united with the neighbouring parts by the effused lymph.

MAYOR (*b*) has modified this practice, by forming at the abdominal ring a *longitudinal fold of skin* varying in size according to the bulk of the rupture and the width of the abdominal ring, to the middle of which corresponds a line drawn over the middle of the hernial swelling; through the base of this fold of skin, held up by the fingers, a needle, armed with a double thread, is to be passed, the ends of which being separated on each side, are to be tied on a piece of bougie, or on a piece of cotton, or of sponge properly tied together. The number of stitches is determined by the size of the fold. In children the first stitch is to be made over the middle of the abdominal ring, at other times, the stitches may be commenced where you please. If the abdominal ring be wide, and the other circumstances unfavourable for contraction and keeping up the rupture, it is then necessary to bring the stitches nearer, and to increase the size of the substances which are held together by the threads. In slight cases, and with quiet, intelligent patients, no bandaging is used; slight compression

(*b*) Sur la cure radicale des Hernies. Paris, 1836.

upon a thick layer of wool by means of a fitting truss, or a neckerchief fastened upon the hip, is always requisite, especially in children and restless patients, and in large ruptures which are with difficulty kept up. The threads may be removed from the sixth to the ninth day, and a truss must be worn for a shorter or longer time afterwards.

1159. **Belmas** (*a*) attempts to effect merely adhesive inflammation, by introducing goldbeater's-skin into the hernial sac, which he at first passed in, as an empty, dry bladder, by an incision through the sac, and then inflated it; but of late he has pursued the following plan:—After the rupture is completely returned, the sac and its coverings are to be raised with the fingers of the left hand in one fold, in front of and parallel with the spermatic cord, and through its middle, above the abdominal ring, a trocar-like instrument, divisible in the middle, is to be thrust. The operator now allows the hernial sac to slip from between his fingers, so that the fold is formed by the skin alone. An assistant holds this fold, and whilst the hernial sac is fixed by the thumb and forefinger, applied above and below the instrument, the latter is to be thrust forward till the union of the two canals corresponds to the interspace between the walls of the hernial sac. By the peculiar mechanism of the instrument the two canulas, after the removal of the trocar-points, are drawn asunder, and both walls of the hernial sac separated. The assistant lets go the fold of skin, grasps the canula corresponding to the trocar-point, whilst the operator holds the other canula, and through its aperture introduces with a probe four or five thin cylinders of jelly covered with goldbeater's-skin, in various directions, into the neck of the hernial sac. The canulas are then removed, and a truss is put on, the pad of which acts where the cylinders of jelly are placed, and is to be worn at least for four months, constantly. The patient may after the operation follow his business. The cylinders of jelly are soon absorbed. The goldbeater's-skin resists absorption longer, and excites slowly in the hernial sac an adhesive inflammation, which is confined to the parts in immediate connexion with the foreign bodies.

Walther's proposes to inject animal fluid, the patient's blood, into the hernial sac.

1160. The decision as to the performance of the radical cure for reducible rupture in general, and on the different modes of treatment in particular, must be guided by the following circumstances. In consequence of the very greatly improved construction of trusses of late years, the necessity for the so-called radical operation is, in comparison with former times, quite another thing, as thereby every reducible rupture can be retained in its proper place, and a cure often be effected by the proper wearing of a truss. All the modes of operation mentioned are more or less dangerous, especially cauterizing, tying, and stitching up the hernial sac, and the

---

(*a*) Recherches sur un moyen pour déterminer des inflammations adhesives dans les cavités séreuses. Paris, 1829.—Cliniques des hôpitaux de Paris. 21st Aug., and 11th Sept. 1839.—Revue Medicale, March, 1838.—**Von Walther**, Ueber die Herniotomie als Mittel zur radicalen Heilung der Brüche; in Journal für Chirurgie und Augenheilkunde, vol. xxvi. pt. iii. p. 363. (Engraving of the Instrument.)

introduction of tents, as the inflammation thereby excited quickly spreads over the whole of the *peritoneum* and the intestines. Therefore, also, many of the earlier adherents to this or that practice, have, after unfortunate results, given them up entirely; and although some, for instance, KERN, have always observed fortunate results, and only one case terminate fatally, yet these assertions are too greatly opposed to the experience of others, to enable us to yield them entire belief. All the modes of treatment, at the same time, in reference to their *permanent* consequences, are uncertain, and the statements of the cures are confined principally to immediately after the operation. Although the external abdominal ring and a part of the neck of the hernial sac be loosed, there remains (in external or oblique inguinal rupture) the opening of the internal abdominal ring into which the intestines again enter, and by gradual subsequent absorption of the effused plastic mass, and the thinning of the scar resulting therefrom, the rupture enlarges outwardly. In many cases, if the enlargement of the opening out of which the vessels of the testicles and thighs protrude, be the consequence of a bad, lymphatic constitution, apertures are formed in other parts of the belly, and if the rupture be kept up at one part, it will be seen to project at some other part. In gouty, otherwise healthy subjects, in a small rupture of not long continuance, if the sac be not thickened and not united to the neighbouring parts, the result may be at first favourable. Increased pressure, with the supine posture, is of all treatment the least dangerous, and may be attempted in all cases, although even herewith, severe inflammation and gangrene (MANGET, RICHTER) and even death (WILMER, SCHMÜCKER) have been observed. As to this mode of treatment, the methods of GERDY, BELMAS, and MAYOR, are arranged according to their less danger. GERDY has up to the present time had the greatest success; I have, however, seen a recurrence of the disease, and according to BRESCHET (*a*), the results have in several instances been unfortunate. If, as in old ruptures where the sac adheres to the aponeurotic opening, (the abdominal and femoral ring,) and consequently a mere inthrusting of the skin be not possible, the hernial sac be thrust in and held with loops, dangerous inflammation may easily occur; and this is still more likely to occur, if, as in BONNET's practice, be adopted. In this respect MAYOR's treatment is least attractive. I consider as some of the indications for the so-called radical cure those reducible ruptures, which even in the above-mentioned supine posture, with the application of a truss, cannot be certainly kept up, especially in young persons, GERDY's or MAYOR's treatment is the most proper; but a truss must always be worn subsequently. The possibility of an unsuccessful, and the probability of a not permanent result must not be withheld from the patient's knowledge. The patient's wish to be cured *radically*, at all hazards, and to get rid of the use of the truss must not, according to the hitherto noticed results, determine the Surgeon to operate.

Opinions in reference to the value of the radical operation for reducible rupture, are in modern times much divided, many rejecting it as dangerous and ineffectual, (BOYER, DUPUYTREN, LAWRENCE, and others,) and it has been attempted to be effected by continued pressure alone (RICHTER, LANGENBECK, ZANG.) Few have allowed its general employment (KERN, VON GRAËFE.) Some confine it to certain cases (SCHREGER, VON WALTHER, and others.) SCHREGER especially lays down the following indications:—1. To remove certain local conditions and to render the application of a truss possible, for instance, in the complication of inguinal rupture with hydrocele, and indeed

---

(*a*) Journal VON GRAËFE und VON WALTHER, vol. xxii. pt. iv. p. 657.

in a common hernial sac; in young subjects, with large ruptures, which cannot be properly kept in their place by any truss; in partial adhesions between the protruded parts and the hernial sac, or the testicle in congenital rupture. 2. In very fat or thin persons in whom the truss always shifts, for the purpose of restricting by the operation, the protrusion of the rupture, and thereby to strengthen the effect of the truss. 3. When scarcely any truss will fit; for instance, in lame persons, or if the testicle lie completely in the groin. 4. Questionable femoral ruptures, because in these there is little benefit from insecure application of the truss, and the danger being greater in existing strangulation. But in all these cases, the rupture can be kept up by the proper construction of the truss, and its application in the supine posture. If hydrocele exist at the same time, repeated puncturing answers the purpose better (*a*).

[English Surgeons have rarely employed either of the methods proposed for the radical cure of ruptures, except the constant application of a truss, which, however, is admitted to be rarely successful, except in young persons and very recent ruptures. Astley Cooper removed the entire sac in a case of femoral rupture, and "passed stitches through its mouth, so as to bring the edges into perfect contact. * * * On the sixth day the ligatures came away, and the wound was healed on the tenth. A month afterwards I saw the woman," says he, "and was surprised to find that another *hernia* had formed on the same spot, which was already as large as that for which the operation was performed. * * * It appears, therefore, that the removal of the sac will not prevent a return of the disease; and, indeed, when it is recollected that the aperture from the *abdomen* continues of the same size after, as before the operation, and that the *peritoneum* will still remain the only obstacle to the descent of the intestine; it does not appear probable that this highly extensible membrane should succeed in preventing a return of the same *hernia*, the just formation of which it was unable to resist." (p. 62.) Astley Cooper objects to the plan of making a ligature round the mouth of the hernial sac, not only that its object, gradually to cut away the sac, is inefficient, as shown in the preceding observation, but also because "it cannot even be securely done; for *first*, the spermatic cord is often divided by the sac, so that one part of it passes behind, and the other before, or on the side of the sac. When this happens, it would be extremely difficult, if not impossible to conduct the operation in such manner as to avoid injuring parts which should never be touched. *Secondly*, this operation is founded on mistaken ideas of the hernial sac; for a ligature applied as proposed, at the abdominal ring, if it cut through the sac, must leave a *hernia* above it, with a sac still open as before; and the ligature cannot be employed to the part of the sac lying above the ring, without splitting up the tendon of the external oblique muscle, which would take off so much of the natural support of the parts, as almost certainly to allow of a future descent. *Thirdly*, the danger of the operation is a principal objection. A ligature applied around a part of the *peritoneum* must inflame it; and as this membrane is continued without interruption along the sac into the cavity of the *abdomen*, the inflammation will follow the same course, and expose the patient's life to hazard." (p. 62.) In support of this latter objection, Cooper refers to Petit's (*b*) experience. "I opened the tumour," says the latter, "and replaced the *omentum*: I then detached the sac, and tied it as I had seen done, and dressed my patient. In two hours time I was much surprised at receiving a message that he felt great pain over the whole belly, and severe gripings. I hastened to the patient, fancying that the intestine might have slipped into the ring and become strangulated; but when the dressings were taken off, and nothing was found in the wound, I concluded that the mischief had been caused by tying the sac. I cut the ligature and removed it, and dressed the parts simply; the symptoms were immediately relieved, and ceased entirely in an hour. This is not the only observation I have made on the subject; all I have seen has confirmed me in the opinion, that the ligature of the sac, or in other terms, of the *peritoneum*, since the sac is formed by that membrane, may bring on symptoms very like those caused by strangulation of the intestine. I cannot doubt that those whom I have seen perish after the employment of the *punctum aureum*, have died from inflammation of the belly, caused by tying the sac." (p. 339.)

Lawrence also comes to the same conclusion in regard to the proposed operations for the radical cure of ruptures.—"I cannot believe," says he, "that any one of the methods now under consideration is calculated to attain the proposed object. Why does the rupture return after the operation? Because the ring has been enlarged by the previous protrusion, and is still further weakened by the incision necessary for removing the stricture. This state of the tendinous openings would not be altered by closing the

---

(*a*) Compare Hesselbach, p. 245; Jacobson, p. 77; Sigmund; in Hufeland's Journal, March, 1841.

(*b*) Traité des Maladies Chirurgicales, vol. ii.

mouth of the sac, even if we could accomplish that object. We must reject the ligature on account of the danger inseparable from its employment, and we have no sufficient reason for placing confidence in scarification of the sac or in its removal by dissection. In many instances these latter methods would be neither easy nor free from danger. Hence we account for the circumstance that all these various methods have become completely obsolete." (p. 321.)]

1161. The *treatment* of *strangulated rupture* must be directed according to the different character and severity of the symptoms; in reference to which, suitable remedies must be employed with due circumspection and choice; too violent attempts, and especially too frequent changes, and again, new experiments which have in so great number been proposed and boasted of, are to be avoided. But too frequent is the course of strangulation hastened by improper treatment, and the patient's condition rendered worse. The more acute the inflammation, the more dangerous is it.

1162. Inflammatory strangulation requires blood-letting, especially if the symptoms be severe, if the patient be strong, the rupture and the belly very painful. Small pulse, cold limbs, pale countenance, must not prevent blood-letting, as these are the peculiar symptoms of violent inflammation of the belly. The earlier bleeding is performed, and the more blood is taken at once, even till fainting is produced, the better is its effect. Leeches may also be applied about the region of the rupture, and because they usually here produce an erysipelatous inflammation of the skin, they may be applied about the *rectum*, (BIRAGO,) (*a*) and cold fomentations, at the same time upon the hernial sac or cold sprinklings to the rupture. If the rupture be very tense and painful to the touch, it must be attempted by these means first to produce a favourable change, general and local relaxation, before the *taxis* is employed, which must be done in the most dexterous manner, according to the above-described rules. If the rupture be less painful, we may commence the treatment with the *taxis*, and if this be not successful, the above treatment must precede subsequent attempts with the *taxis*. All internal remedies, especially purging, are in this strangulation hurtful; even calomel, which has been recommended by many, (RUST, SEILER, and others,) I have always noticed as having only an injurious effect. The patient must merely take mild drinks, for example, almond milk, gum water, and the like, in small quantities. Clysters in severe inflammation, merely soothing, with the addition of castor oil, and in diminished inflammation, of infusion of tobacco or tobacco juice, are extremely efficient.

Tobacco clysters are not to be considered as irritants, but as narcotics, and the employment of *belladonna* or *hyoscyamus* are similarly circumstanced, only the operation of the tobacco is less dangerous; from it ensue a disposition to *nausea*, to fall down, faintness, slow pulse, and diminution of the tension of the rupture. The effect of the tobacco juice and infusion is similar, but the tobacco-juice clysters are very troublesome, the necessary preparations for which are not always at hand. For the infusion, from half a drachm to a drachm of tobacco is used in from twelve to sixteen ounces of water, for two clysters. When injurious effects have been observed, the quantity of tobacco was too large.

[Tobacco clysters are very uncertain, and have been occasionally very dangerous remedies; as the strength of the infusion varies considerably according to the freshness and goodness of the tobacco leaves, of which it is scarcely possible to judge. The use of tobacco clysters, which was formerly much urged by ASTLEY COOPER in cases of strangulated rupture, is now much less practised than formerly; indeed I have not known it used at St. Thomas's either by my colleagues or myself for many years.

(*a*) Compendio di Osservazioni cliniche sul vantaggio delle Mignate applicate all' Ano nelle ernie inguinale et addominali incarcerate, e sulla potassa caustica applicata in diverse malattie di carattere linfatico. Milano, 1821. 8vo.

We prefer, in the event of the failure of the *taxis*, after warm bath and quick full, bleeding, at once to resort to the operation, considering it the most safe practice.—J. F. S.]

1163. If the symptoms be less severe, and if complicated with spasm, warm bathing, rubbing in volatile ointments, with opium or oil of henbane upon the belly, tobacco clysters, cold applications upon the rupture, and in powerful persons, a large bleeding in a very hot bath, are most efficient remedies, after which sudden relaxation follows, and the reduction is effected. Here also internal remedies are ordinarily hurtful, as they increase or excite vomiting, as purgatives, with whatever addition, ipecacuanha in repeated doses, and so on. A simple emulsion with *aqua lauro-cerasi* is, among these, the most proper. The *taxis* must here also be at first attempted, and if it do not succeed, must be repeated after the remedies mentioned.

1164. In *Chronic Strangulation*, when, from collection of stools, but without any inflammatory symptoms or vomiting, or when these, though rarely, are present, stimulating clysters of vinegar and water, soap and water, solution of salts with castor oil, solution of tartar emetic, infusion of senna, tobacco clysters, cold applications upon the rupture, and internally purgatives, in very chronic cases calomel alone, or with opium and colocynth extract, (A. Cooper,) even with jalap or croton oil, (von Walther,) have been directed. But when vomiting has set in, the latter remedies always render the patient's condition worse. With the *taxis* it must always be attempted to compress the rupture, in order to return part of the collected stool. When inflammatory symptoms have come on, the above-mentioned treatment must be employed in correspondence with circumstances.

1165. The *taxis* must be employed in strangulated, in the same way as in reducible rupture. The patient, after having emptied his bladder, must lie in such posture that the seat of rupture be raised, and the walls of the belly properly relaxed; in inguinal and femoral ruptures with the rump raised, the chest bent slightly forwards, and the thighs drawn up towards the belly, but not separated from each other. The practitioner stands on the right side of the patient, grasps the hernial swelling with the fingers of his right hand, and places the fingers of the left in the region of the mouth of the sac, and endeavours, by alternately pressing the rupture together, and in the direction of its escape, to press it back into the belly. In small, for instance, femoral and umbilical ruptures, the fingers of both hands may be applied around the swelling to compress and return it. Herewith the rupture must be carefully moved from one side to the other, kneaded between the fingers, and the pressure only gradually increased. Violent pressure is to be avoided, because severe pain, increased inflammation, and even rupture of the bowels or of the hernial sac may ensue, and the *taxis* must not be too long continued; but it must also be remembered, that without pain scarcely one strangulated rupture can be reduced. These manipulations may be continued for from a quarter to half an hour, and in chronic strangulation, even longer, and with greater force. We should endeavour to withdraw the patient's attention to some object, and forbid all effort and straining. If the *taxis* be unsuccessful, the patient must be left quiet in the same position, with the thighs supported in the hams; and it must be considered, according to the circumstances, what further remedies are to be employed, and whether the attempts with the *taxis* should be repeated. Nothing is more injurious than excessive violence and rough handling. I have observed not unfrequently, that by keeping quiet, after the most careful attempts at reduction have failed, the rupture returns either of its own accord, or with a slight assistance on the part of the patient.

1166. If the reduction succeed, the symptoms usually soon cease, and relief of the bowels ensues either of themselves or by the use of purgatives and clysters (1). If the inflammatory symptoms continue, they require corresponding treatment. The abdominal ring should always be examined with the finger, in order to ascertain that no part of the rupture remain in it, as may be the case, especially in external inguinal ruptures, in which I have several times observed, after a tolerably bulky, and in one case, even very large rupture, had returned, and the external ring was free, that there was strangulation of a small portion of intestine at the inner ring, which rendered the operation necessary. But if under the treatment prescribed there be no satisfactory change in the rupture, but on the contrary, it become more hard and painful, the belly tense, and the vomiting more frequent, neither the use of other remedies, nor attempts with the *taxis* are to be persisted in, but the operation must be had recourse to.

The treatment proposed for strangulated rupture, in reference to the employment of remedies internally and externally, and of the *taxis* is very various. Although these several modes of treatment may be grounded on many good results, the above-described method must be considered most preferable, if it be employed with discretion and proper circumspection.

The position of the patient under the *taxis*, with his feet or knees upon a person's shoulders; the *vertical* position of the body, in order thereby to effect the return of the intestines through their proper tendons, and the application of ice poultices upon the rupture (Ribes) (*a*), with the *pelvis* raised and the head depressed; the posture upon the opposite side, with the thigh drawn up on the affected side (Hey); even the position on the knees and elbows. Continued pressure on the rupture with a weight or bladder of quicksilver of from two to five pounds; or by the patient's hand. Shaking the whole body by driving in a wheel-barrow (Preiss); injection of air into the *rectum*, and drawing it off with a clyster-pipe. The introduction of a thick elastic tube through the *rectum* into the sigmoid flexure of the colon, after O'Beiern's manner (*b*), who considers the collection of the intestinal gases and the spasmodic closing of the *rectum* as the most common cause of strangulation. The application of dry cupping-glasses about the hernial swelling, or of a glass bell, out of which the air may be pumped by some strokes of an air-pump, till the rupture is as high again, after which it either returns of itself, or is easily reduced with the *taxis* (*c*). Clysters of *hyoscyamus* and *belladonna*; a mass of *belladonna* ointment smeared over the interior of the *rectum*; or a bougie smeared with extract of opium and of *hyoscyamus*, of each two grains, passed into the *urethra* (Ribieri, Guérin). Purgatives of all kinds; rubbing of croton oil on the belly; galvanism (*d*); clysters of lead wash (Nember, Rennerth, Preiss); tartar emetic (Church); muriate of morphia (Bell.)

[(1) It is perfectly true, that in general after reduction the symptoms of strangulation subside; but now and then they do not, which may depend upon the damaged condition of the bowel, or simply on the existence of *peritonitis*. Instances of the latter are not very uncommon, and can scarcely be distinguished from the symptoms of strangulation, except by the absence of the hernial swelling. Of the former I had an example under my care in 1840, which was a source of great anxiety, and terminated fatally.

Case.—J. S., aged seventeen years, ruptured himself on the right side whilst lifting hampers into a cart in the afternoon of

Nov. 30, and immediately observed in the *scrotum* a swelling as large and as long as his thumb. Half an hour after he began to vomit, and continued to do so through the night. On the following morning the *taxis* was unsuccessfully employed, and afterwards

a few leeches; some medicine was given, which was rejected; he continued vomiting during the day, had not any relief from the bowels, and suffered pain in his belly. Next morning the rupture was reduced and a truss applied, but removed two hours after, as it was too large. During the day he was relieved of the pain, but vomiting occurred five or six times, and especially on attempting to take anything into his stomach. Towards 8 P.M. the swelling reappeared, about half the former size; the vomiting became more frequent, and the pain in his belly increased.

Dec. 3, 2 A.M.—He was bled nearly to fainting, and the rupture returned; a cold mixture in a bladder was applied (for what reason did not appear) to the region of the swelling, and replaced continually as it became warm. The vomiting, constipation, and pain continuing, he was brought to the hospital at

½ *past* 3 P.M.—He was immediately put in the warm bath, where I examined him, but even when standing up could only observe a slight fulness in the right groin, probably from the leeches, and very deeply a small indistinct swelling not exceeding the size of a small bean, between the abdominal rings; it neither dilated on coughing, nor yielded to pressure. I could pass my finger readily into the external ring. His belly was full and tympanitic, and he complained of pain and tenderness specially about the hypogastric region. The pulse was small and quick; but he had not any anxiety of countenance. I could not feel satisfied of the existence of a rupture, and therefore ordered five grains of calomel and an injection of infusion of senna and salts, which was retained; but an injection of castor oil in the course of the evening returned immediately.

11 P.M. I made another careful examination, in consultation with my friend CALLAWAY, and I thought I felt a slight gurgling, but very doubtful; it could not be felt again, and we both were satisfied that the swelling was merely the spermatic cord. We therefore ordered a grain of calomel, and half a grain of opium, every hour, with a castor-oil injection immediately: and thirty leeches to the belly, with subsequent fomentations, considering his attack to be peritoneal and enteritic.

Dec. 4. The bowels continued obstinately costive throughout the whole day, except a very small quantity of thin watery stool once in the afternoon, and again in the evening, although injections were thrice thrown up. The vomiting did not recur, but he felt nauseated, and the tenderness and tympany of the belly increased. When I saw him at nine in the evening, his tongue was much loaded, and the gums reddened, but without soreness or mercurial smell. The little enlargement in the inguinal canal still remaining, I fancied I again felt a slight gurgle, but it ceased almost immediately. The calomel and opium were ordered every three hours; half a drop of croton oil directly, and to be repeated two hours hence, if requisite; thirty leeches to the belly, and fomentation. I had scarcely left him when he vomited about a pint of dark-green and very fetid fluid. The croton oil was taken at ½ *past* 10 P.M., and after an hour producing only a small thin motion, the second dose was given. Two hours after, his bowels acted again, and he again began to vomit, and vomited and passed thin, but more fæculent motions five or six times before

Dec. 5, 7 A.M. when he became quiet, and two hours after took some bread and milk, which he retained till

11 A.M., and then rejected; his countenance is now much shrunk and flushed, but he is cheerful, and wishes something to eat: pulse 100, and small. He has much pain in the belly, but it is less distended. An hour after he had another loose motion.

2 P.M. In consultation with my friends GREEN and CALLAWAY, we were satisfied that no intestine was down, and the slight fulness already mentioned had entirely disappeared. The calomel and opium which had been withheld at the last period, was ordered to be resumed, and a mustard poultice applied over the belly. Soon after the application of the poultice, vomiting of thin, yellow, acid-smelling fluid recurred, and continued frequently till evening, when I ordered him effervescing mixture, with large excess of alkali, but without benefit, and the vomiting continued through the whole night and following day, not being at all checked by two minim doses of hydrocyanic acid, with compound spirits of ammonia, every six hours. As his mouth was untouched by the calomel, I ordered on the morning of this day,

Dec. 6, that he should rub in a dram of mercurial ointment, with five grains of camphor, every four hours; a large blister over the whole belly, and a colocynth injection.

8 P.M. No motion since noon yesterday; the vomiting continues, and he is much sunk. To take a grain of solid opium every six hours, and have some brandy and arrow-root.

Dec. 7, 4 P.M. He died, having continued to vomit since the last report, and not having had any relief from the bowels.

Examination.—After raising the tendon of the external oblique muscle from the inguinal canal, the edge of the internal oblique was seen uplifted by a small dark-coloured tumour about the size of a hazel nut, which was evidently a hernial sac and contained dark-coloured fluid. The internal oblique and the transverse muscles were then carefully divided up to the internal ring, to which the sac was easily traced, and the latter having been carefully opened about its middle, about a drachm of *serum* escaped. The sac was cut up to the internal ring, through which a very small knuckle of dark-coloured but shining intestine protruded. The belly was next opened; it contained no fluid, and little apppearance of inflammation, except a thin film of adhesive matter slightly gluing together the intestines in the right iliac pit. The abdominal muscles having been completely turned down, about eight inches of very dark-coloured yellowish green intestines were exposed, distended immediately above the portion of gut in the mouth of the sac, with thin fæculent matter like his last stool; an inch of the bowel below the sac's mouth was of the same dark colour, and suddenly terminated by a distinct mark of strangulation, upon which, beneath the *peritoneum*, fibrin had been poured out. Below this point the gut was healthy but contracted. The portion of intestine in the sac was about two-thirds of its tube, the part nearest the mesentery, being quite above the internal ring. In examining further, this protruded piece of gut dropped out, and there was not found upon *it* the slightest mark or appearance of strangulation.

From this examination, I presume, that the strangulated bowel had been returned by the medical man who last saw him; that the strangulation had been sufficiently long to destroy the vitality of the intestine, which had therefore never recovered itself; that the portion of intestine found in the mouth of the sac, had been forced in by the vomiting but that *it* had never been strangulated nor incarcerated, nor had probably been there constantly, through the course of the disease, though it might have been occasionally. by the effort of vomiting; and that the costiveness depended not on the tube of the bowel being impervious, but on its death having destroyed its functions, and that the stools passed were merely forced by their quantity through the dead intestine.—J. F. S.]

1167. The decision as to the proper time for the operation, especially depends on the kind of strangulation, on its severity and duration, on the constitution of the patient, and on the effects which the previous remedies had produced (1). In inflammatory strangulation, in small ruptures, which arise suddenly from external violence, or in those where the strangulation is at the mouth of the sac, (*par.* 1135,) in young vigorous persons, the operation must not be delayed; if by the preceding treatment reduction have not been effected, or if the painfulness of the rupture will permit no further attempt at reduction. It is often necessary within the first eight or twelve hours. In such cases can the advice of KERN and WATTMANN be alone applicable, not uselessly to waste time by attempting relief with external and internal remedies, but immediately to employ the only helpful remedy; to wit, cutting into the rupture. In spasmodic and chronic strangulation, the operation may be delayed; very frequently repeated attempts at reduction should, however, be avoided, and after the most powerful remedies have been employed, it is better to resort earlier to the operation, than by further delaying it to put the patient's life in greater danger. But the operation is in these cases specially indicated, if an inflammatory condition be superadded, especially in old persons. In general, the longer the operation is delayed, the more unsatisfactory is the *prognosis*, as the danger is less from the operation itself, if properly conducted, than from the degree of inflammation and the circumstances thereon depending.

[(1) The invariable rule in all cases of rupture in which symptoms of strangulation exist, be they slight or severe, if the *taxis*, after warm bath and bleeding have been unsuccessful, is without loss of time to proceed to the operation, as the most safe for the patient. For the damaged state of the intestine is frequently not indicated by corresponding severity of symptoms, as is well known to every one who has often operated in strangulated rupture. Every hour, therefore, which defers the operation adds to the patient's danger; on which account we cannot operate too early, when satisfied that strangulation cannot be relieved without.

Occasionally it happens that patients will not submit to an operation for strangulated rupture, and nothing then remains but to persist in the employment of one or other of those remedies which have been proposed. The tobacco clyster is now therefore permissible, and should be resorted to, and the continued application of ice poultice (ice roughly pounded or a freezing mixture, consisting of hydrochlorate of ammonia and nitrate of potash, five ounces of each with a pint of water,) in a bladder upon the swelling, which sometimes succeeds; but the condition of the skin should be attended to during its use, as it may become frost-bitten, and though the rupture may be reduced, the skin may slough, which happened to a patient of the elder CLINE. Sometimes the patient having withheld his consent for many hours, being at last worn out by the vomiting, will submit to an operation; the question then comes, should it be performed under unfavourable circumstances? I think it should; for, without an operation, he must certainly die, and with it he has a chance, however slight, of recovery. Indeed I think the operation for strangulated rupture should always be performed, if the patient be not *in articulo mortis*.—J. F. S.]

On Strangulated Rupture in particular, the following writers may be consulted:—

ZIMMERMANN, Beobactungen der beruhmtesten Wundärzte neuerer Zeit zur Erlaüterung der sichersten Behandlungsarten eingeklemmter Brüche. Leipzig, 1832. fol.

STEPHENS, Treatise on Obstructed and Inflamed Hernia. London, 1829.

RUST, Ueber die rationelle Behandlung eingeklemmter Brüche; in his Magazin, vol. xxix. pt. ii.

SINOGOVITZ, Anleitung zu einer zweckmässigen Manualhülfe bei eingeklemmten Leisten und Schenkelbruchen. Danzig, 1830.

1168. The operation for strangulated rupture proceeds by the following steps:—*first*, The incision of the skin; *second*, The exposure and opening of the sac; *third*, The dilatation of the neck of the sac or of the abdominal ring; *fourth*, The return of the intestine.

Previously to the operation, the urinary bladder should be emptied, the seat of the rupture, if hairy, shaved, and the patient so placed on a narrow table, covered with a mattress, that the rump and chest be raised, and the belly properly relaxed; or so upon the edge of a table, that the feet may rest on and be supported by a stool.

1169. The skin above the hernial swelling is to be raised into a transverse fold, the one end of which is given to an assistant, and cut through with a bistoury (1). By means of a grooved director introduced into the angle of the wound, the incision is to be enlarged upwards and downwards, so that it extend beyond the swelling in both directions (2), if the tension of the skin do not permit the formation of a fold, the incision must be made freely, the skin being drawn aside by the thumb and forefinger of the left hand. As there are ruptures without sacs, or as the sac may be torn, the incision through the skin must be cautiously made, and the director used as much as possible.

[(1) Lifting up a fold of skin over the rupture, and either cutting through it, as here recommended, or piercing it with a bistoury, and cutting out, is, I think, bad and dangerous practice; for it cannot always be ascertained what the thickness of the coverings of the sac are, or indeed whether there be any other than the skin, and therefore, in not very dextrous hands the sac may be opened at once, and the gut injured. This mode of commencing the operation may seem smart and flashy, but it is dangerous and improper, and entirely devoid of any good reason for its performance.

(2) In inguinal, or rather in scrotal rupture, it is better that the cut made lengthways, should not extend below the bottom of the tumour; it should terminate an inch above it, as room in the operation is not wanted there. The cut should extend above the swelling, otherwise the stricture is so inconveniently deep, that it will commonly be necessary to

enlarge the external wound after the sac has been opened, and before the division of the stricture can be made.

In femoral, umbilical, and other ruptures, it is not needful to extend the cut beyond the swelling, because the flaps usually made either by the ⊥ or crucial cut, afford ample space for the continuance of the operation.—J. F. S.]

1170. The exposure of the sac requires care, as the coverings are very different, and in old ruptures considerably degenerated. At the part where protected from any other injury, or where fluctuation is most distinct from the fluid contained in the sac, the coverings must be taken hold of with a pair of forceps, raised up in a heap, and divided with the bistoury held flat (1); this is to be repeated till the sac is laid bare, which is known by its shining surface (2). The blood flowing from these cuts must be carefully absorbed with a sponge. The hernial sac itself should be raised in a similar manner, and cut into, from this opening a little fluid usually escapes; for though the *omentum* be fallen over the surface of the intestine, the shinyness and smoothness of the sac show the practitioner that he has penetrated its cavity (3). The edge of this opening is to be raised with the forceps, and enlarged with blunt-ended scissors, till a finger can be introduced into it, upon which the scissors (4), or button-ended bistoury, should be introduced, and the opening of the sac increased upwards and outwards throughout its whole length (5). If on opening the hernial sac, an adherent part be lighted on, the opening must be enlarged at some other part, till the finger can be introduced, to destroy the adhesion, if it be gelatinous, or if membranous, to divide it with the knife. In firmer fleshy adhesions, we must proceed as will be hereafter mentioned (6).

If after these appearances, it be doubted whether the sac be opened or not, the swelling is to be pinched up with the thumb and forefinger into a fold, and that held between them gradually allowed to escape, when it is distinctly felt whether there be merely intestine or the hernial sac also.

[(1) In dividing the coverings of the sac, I prefer, after the skin has been completely cut through, scratching with the end of the probe or director, till a layer of the cellular tissue be penetrated, and then introducing the director and dividing upon it; after which a second and other layers are to be divided in similar way, even to the opening of the sac itself. This is much safer than nipping up with the forceps and opening with the knife laid horizontally, which, however, cautiously used, may, in opening the sac itself, risk the puncture of the intestine; an accident which once occurred to myself when I was a young operator.

(2) The hernial sac cannot always be distinguished by its shining appearance, for occasionally it is thick and opake, especially after long wearing a truss; and I have again and again seen the sac opened when the Surgeon supposed he was far from having reached it. Also if, as in rare cases, it happen that the sac and its contents be glued together more or less completely, this distinction does not hold.

(3) The most certain proof of the sac being opened, is the escape of the fluid in greater or less quantity contained in it, which is proportioned generally to the length of time the patient has had the rupture, and also of the existence of strangulation. It is a most satisfactory indication of the course of the operation, but the Surgeon must not expect always to have it. During the course of the last few months I had a case of strangulated rupture, in which not a drop of fluid escaped when the sac was opened.

The colour of the fluid escaping, when the sac is cut into, varies considerably; sometimes it is almost colourless, sometimes red as blood, and Callaway told me of an instance in which even a clot of blood was found in the sac; the case, however, did well.

(4) I prefer the director and knife to the scissors, and throw aside even the director immediately the aperture is sufficiently large to admit the finger, which is always the best guide for the knife, and the greatest protection to the contents of the sac.

(5) There is no need, as already mentioned in regard to the external wound, to open the sac down to its bottom; but it *must* be divided up to the stricture.

(6) Whenever an artery is disposed to bleed, if divided whilst cutting through the several coverings, it is better at once to tie it, as the bleeding often causes confusion.—J. F. S.]

1171. In many cases, when the strangulation is not considerable, or depends on the peculiar position of the intestines, their entanglement, or their circular enclosure by the *omentum*, the protruded parts may be returned when they are properly untwisted; or when the part of the intestine at the seat of strangulation has been a little drawn out, and by a gentle pressure, it has been attempted to return the contents of the bowel into the belly. If the intestine be strangulated in a fold of the *omentum*, this must be freed with the bistoury, if the intestine cannot easily be drawn out of it.

[In the College Museum is a very remarkable instance of strangulation of a small intestine, by a smooth round cord, two and a half inches long, and about a line thick, extending from the end of a *diverticulum* on the *ileum* to the mesentery, about an inch and a half from the edge of the intestine. In St. Bartholomew's Museum there is a similar case of a *diverticulum* from the small intestine to the mesentery, forming a circular hole, in which the gut is strangulated. The patient was subject of obstinate costiveness, and died in four days. In St. Thomas's Museum there is an instance of strangulation of small intestine by a band from the ascending *colon* to the mesentery. And at St. Bartholomew's a preparation of the small intestines of a child of seven years old, strangulated by a narrow thread-like band from the mesentery; he was admitted for constipation, and died fourteen days after.—J. F. S.]

1172. If reduction cannot be thus effected, the seat of strangulation must be dilated, which may be done either by *cutting* or by *stretching*.

1173. *Dilatation by cutting* is effected in the following way:—The intestine is to be withdrawn in the most careful manner by an assistant, from the place where the cut is to be made; the sac should be drawn somewhat outwards with the thumb and forefinger of the right hand, and the tip of the left forefinger is to be introduced between the intestine and the neck of the sac; a straight or curved narrow bistoury, with a blunt end, should be introduced flat upon this finger, its cutting edge directed towards the place where the cut is to be made, and the seat of strangulation cut into by raising the handle of the knife, or by pressing its edge up with the finger of the left hand; but if the strangulation be so great that the finger cannot be introduced, after drawing down the neck of the sac, a director, curved according to circumstances, and oiled, is to be introduced between the intestine and the seat of strangulation, its groove turned towards the part where the incision is to be made, its handle so held with the fingers of the left hand, that they separate the intestines from the director, and give it such position, that its point rests against the inner surface of the *peritoneum;* and then upon its groove the button-ended bistoury should be introduced. If the seat of strangulation be deep, it is more safe to draw the intestines a little down, so as to be able to see the seat itself. The direction of the cut should always be such as to prevent serious injury; and its size such that the forefinger may, without violence, be introduced at the part where the stricture was situated. It is then to be ascertained by the introduction of the finger into the belly, whether any second strangulation exist which requires a second dilatation.

There are peculiar instruments for dividing the strangulating part. **Petit**'s straight and curved fork director; **Mery**'s and **Mohrenheim**'s winged director; the *straight* bistoury, with a button or probe end of **Petit**, **Bellocq**, **Brambilla**, **Dzondi**; the *convex* one of **Le Blanc**, **Brambilla**, **Dupuytren**, **Seiler**; the *concave* of **Perret**, **Heister**, **Arnaud**, **Richter**, **Rudtorffer**, **Astley Cooper**, **Langenbeck**, and others, merely a modification of **Pott**'s bistoury, the *concealed* bistoury of **Bienase**, **Le Blanc**, and **Le Cat**.

[In the division of the stricture, the use of the finger, as a guide for the introduction of the blunt-ended bistoury, is far preferable to the director: and being sure that it is by far the safest, I rarely use any other, however tight the stricture may be. If the finger can fairly reach the stricture, and the smallest part of its tip can be introduced, a very little gentle thrusting will make room for the entrance of the point of the knife. In inguinal rupture I do not recollect to have used a director more than two or three times, and but little more frequently in femoral. The director is a very unsafe instrument, where out of sight, for however carefully the intestine may be tended, it will occasionally turn over the director, and be cut in dividing the stricture, which I have seen happen once or twice. When it is absolutely necessary to use the director, in consequence of the impossibility of getting the tip of the finger into the stricture, I have protected the intestine by introducing a spatula between it and the director up to the very stricture. But when this difficulty occurs, it is advisable to lengthen the cut upwards through the skin and coverings of the sac, till the stricture is brought completely and distinctly into view, and then to introduce the director.—J. F. S.]

1174. The *bloodless dilatation*, or that *without cutting*, which is only applicable in those cases where serious injuries, not well to be avoided, forbid incision, may be effected either by the introduction of the finger, or with a proper dilating instrument, (LE BLANC's dilator,) or with a small hook, (LE CAT's S-shaped hook, and ARNAUD's hook;) which is to be carefully introduced between the intestine and the seat of stricture, and therewith extension made, sufficient to render the reduction possible. Bruising of the intestine is scarcely to be avoided.

The bloodless dilatation, first proposed by THEVENIN (*a*), was particularly recommended by LE BLANC (*b*); but although LE CAT, ARNAUD, RICHTER, even SCARPA, and others have conditionally declared for it, in recent times it has been almost entirely rejected, and only applied, by some, (TRUSTEDT, RUST, SEILER,) to femoral rupture, especially, and in a manner to be hereafter described.

[I know no circumstances in which dilatation without the knife is permissible. I should consider any forcible expansion of the stricture, by pulling or dragging with instruments, dangerous and unwarrantable, as it would be ineffectual for the required purpose without more mischief than would result from using the knife.—J. F. S.]

1175. When the obstruction to the return of the intestines on the part of the neck of the sac, or of the abdominal ring has been removed, it depends on the state of the parts contained in the rupture how their return shall be effected. This is often at once possible, without any difficulty; often must the intestine be carefully unfolded, if filled with stool or air (1). That part of the intestine at the seat of strangulation should always be drawn a little down, to examine its condition. The reduction should be effected with the fingers wetted, those parts first protruded, being carefully first returned: thus the mesentery earlier than the intestine, and that before the *omentum*, according to the direction of the aperture through which they have protruded. The forefinger is then to be passed by this opening into the belly, for the purpose of determining that all the parts are returned (2).

[(1) Always before the intestine is attempted to be returned it should be emptied by gentle pressure of its contents, whether air or stool, which renders the reduction easy; whilst if this be not attended to, considerable difficulty is often experienced. Not unfrequently after dividing the stricture, the tonic power of the muscular coat of the bowel will itself empty its contents; or if they be fluid, they will flow back into the intestine canal, the protruded gut become flaccid and be readily returned into the belly. I do not at all consent to the practice of pricking or cutting into the intestine, if it be indisposed to return, on account of its distension with air. I am sure that after dividing the stricture freely, it is not matter of much consequence whether the gut be returned or not by the operator, as most commonly after a short time the air passes along the freed gut, and the protruded part diminishes in size, and if not restrained by adhesions retracts into the belly.

(*a*) Traité des Opérations. Paris, 1696.

(*b*) Précis d'Operations. Paris, 1775. vol. ii. chap. vii.

(2) Although there may be little fluid in the sac, yet it is not unfrequent to have it pour forth freely from the cavity of the belly after the protruded parts have been returned. I recollect having a case in which blood-red fluid escaped so largely that I almost feared I had divided some vessel; however, it ceased before the patient was removed from the table. CALLAWAY tells me of an instance in which, after the return of the intestine, a large quantity of honey-like fluid poured forth, he presumes from an ovarian dropsy having been wounded: the patient, however, recovered.—J. F. S.]

1176. The reduction of the intestine may be rendered difficult or impossible—

1. By *adhesions*,
2. By *disorganization*,
3. By *gangrenous destruction*.

1177. If the connexion of the parts with each other depend on a gelatinous substance, it can be easily destroyed with the finger. Filamentous adhesions having been made tense, may be divided with the knife, the edge of which is to be turned towards the hernial sac, rather than towards the intestine. But if there be a fleshy adhesion between the sac and its contents, the practice is different, according as the adhesion is between the *omentum* and the hernial sac, or between the *omentum* and the intestine. In the former case the *omentum* must be divided, as near as possible to the adhesion, with the knife or with the scissors. If the *omentum* adhere to a considerable extent to the sac, it must only be divided at the neck of the sac, surrounded with some linen overspread with cerate, and when the inflammation has subsided, it should be divided near the abdominal ring. (According to SCARPA, it should be tied and tightened daily till it fall off.) The *omentum* often returns into the belly whilst surrounded with the linen (1). In the second case, after the strangulation is relieved, the intestine must be left quiet in its place, covered with compresses moistened in and often wetted with decoction of marsh-mallows (2). It is frequently observed that the piece of intestine gradually returns into the belly. If it remain partially in the abdominal ring, it becomes covered with granulations and adheres to the integument. The same practice must be pursued in the *natural* connexions between the intestine and the hernial sac, when they render reduction impossible.

If the intestine be so considerably distended with stool and air that reduction is rendered difficult, it must be attempted, after *sufficiently* cutting into the constricting parts and after the intestine has been somewhat drawn down, by gentle kneading, and pressing together, to return partially the contents of the bowel, and to diminish the size of the intestine. In such cases the overfilled intestine has been punctured with a large needle. (LOWE,) with a lancet, (LOEFFLER,) and with the trocar (RICHERAND, JONAS, VON GRAËFE); the latter was successful, and at the same time a loop of the mesentery (*a*) was applied (3).

[(1) If the adhesions between the *omentum* and sac be old and membranous, and easily divided, it is advisable to do so, and to return the *omentum*. But more frequently the adhesions are too short to admit of this; or the surface of the *omentum* is actually glued to, and so consolidated with, the surface of the sac, that it cannot be set free without cutting through. I have had two cases of this kind, in which, having returned the gut, after freely dividing the stricture, I have left the adhering *omentum* undisturbed, and no ill consequences have ensued. But there is a preparation in St. Thomas's Museum, where this practice was pursued, and the gut, after division of the stricture, returned into the belly, yet the symptoms of strangulation continued, and the patient died; and, on examination, it was found that the *omentum* formed a tight cord upon the intestine as it lay transversely behind it, on the brim of the *pelvis*, and completely prevented the passage of the contents of the bowel through it. I do not, therefore, feel certain as to which is the best practice in such cases; but I may state, that

---

(*a*) Journal VON GRAËFE und WALTHER, vol. iii. p. 255.

my cases which were successful happened after the fatal case just mentioned. I certainly should not be disposed to adopt or recommend the practice proposed by CHELIUS, of separating the adhesions at the neck of the sac, and passing a piece of linen round the *omentum*, with the purpose of dividing it at a future time, as I should expect that the presence of such extraneous substance would be likely to excite dangerous inflammation.

(2) As to the adhesions between the *omentum* and gut, if they cannot be easily separated with the finger, they are best left alone, without attempting further separation or their return, to take their chance together, either to remain in the sac, or return of their own accord into the belly.

(3) There is in the Museum of the Royal College of Surgeons of England, a preparation of a portion of strangulated small intestine, which not being returnable on account of the great quantity of air it contained, was cut into, to the extent of an inch, and left in the sac, and the patient died. I cannot imagine there is any necessity for puncturing the intestine to compel its return into the belly, provided the stricture be freely divided; for I know by experience, that if strangulation be relieved, it is of little consequence how much intestine be down. In reference to this point, I recollect the largest scrotal rupture on which I have operated, and in which, before the division of the stricture, there was at least half a yard of bowel down, filled with air; and, after the stricture had been cut through, at least as much more thrust through, so that I almost despaired of getting any back; yet after a time I returned the whole. To my vexation, however, next morning I found my patient had got out of bed to relieve himself on the chamber-pot, and as might be expected, the bowel had descended, and in such quantity, that the *scrotum* was at least as big as a quart pot, and the vermicular motion of the intestine was distinctly seen through the stretched skin. Nothing further was done than to keep the tumour raised above the level of the abdominal ring, by placing a pillow beneath it, and by degrees it returned, and the patient never had an untoward symptom.

If, however, the bowel be filled with solid matter, as hard stool, or apple or potato skin, and its return thus prevented, as well as the passage through it stopped up, an instance of which latter kind is in the College Museum, then the loaded gut ought to be cut into freely without hesitation, as the only means of perhaps saving the patient's life. But such cases I suspect are exceedingly rare.—J. F. S.]

1178. If the *omentum* be converted into a tangled lump, it must not be returned into the belly, because it requires a too large dilatation of the abdominal ring, and this degenerated mass may produce inflammation and even suppuration in the cavity of the belly. The general advice in these cases, is to tie the *omentum* above the degenerated part, to cut it off below the ligature, to return the tied part into the belly, and to fasten the threads externally. The ligature of the *omentum*, however, causes a new strangulation (1).

Experiments on animals, and numerous practices upon man, show that the *omentum*, cut off and without tying, may be returned into the belly without injury (2). But if the vessels of the cut edge of the *omentum* bleed they must be tied singly and the threads allowed to hang out externally, or torsion must be performed on them (3). The recommendation of allowing such diseased pieces of *omentum* to lie out, (POUTEAU, DESAULT, VOLPI, ZANG, and others,) proves the objection, that by fastening the *omentum* in this position, severe disturbance of the stomach and so on may be produced. If the *omentum* be sloughy, the sloughy part must be removed with scissors, and treated in the way prescribed. In these cases, generally the *omentum* becomes adherent to the neck of the sac, which it then closes like a plug.

[(1) I have tied the *omentum*, and cut off the part below the ligature several times, without any of the untoward results commonly, and as by CHELIUS, assigned to this practice.

(2) The largest portion of *omentum* I have known removed was seven ounces and a half, in a case of scrotal rupture, in a man forty-two years of age, under CALLAWAY'S care; he recovered, and the preparation is in the Museum of Guy's Hospital.

Key (a) advises, that "the *omentum* should be unfolded before it is divided by the knife; otherwise the cutting off the *omentum* in a mass prevents all the vessels being seen, and when returned into the *abdomen* they bleed profusely." A case of this kind happened to him, in which he cut off "a large portion of *omentum* with one stroke of the knife, securing the bleeding arteries before returning it to the mouth of the sac. In four hours after the operation blood of an arterial colour began to ooze from the sac, and soon increased in quantity to alarm the dresser. He used pressure and cold to no purpose. Her pulse began to falter, and her face was bedewed with a cold perspiration; and in this state I found her, when early on the following morning I was called to see her. It was evident she had lost a very large quantity of blood, and had she not been possessed of an unimpaired constitution, she could not have supported the loss. I opened the sac, removed the *coagulum* with which it was filled, and was proceeding to look for the bleeding vessels of the *omentum*, when I fortunately observed the hæmorrhage had suddenly ceased. The only ill effect of the hæmorrhage was the disturbance of the adhesive process, and the consequent suppuration in the sac, as she ultimately perfectly recovered." (p. 43, *note*.)

When necessary to remove *omentum* I generally tear it off as far as possible, and afterwards cut through the part which will not tear. I have rarely had occasion to apply any ligatures.

Sometimes if the *omentum* be left, it sloughs; I have seen this happen two or three times without any inconvenience. Astley Cooper (b) mentions a case in which both *omentum* and intestine were returned into the belly, and after the operation the patient complained of severe pain in the belly; the ligatures on the wound in the *scrotum* were removed; on the following day a small portion of gangrenous *omentum* protruded, more and more gradually descended, till the whole which had been protruded appeared in the wound, sloughed, and the patient recovered. (p. 44.)

Hewett has recently (c) given a good account of some cases in which the *omentum* had formed a complete bag around the intestine in strangulated rupture. Although Richter has been stated to have had cases of this kind, yet it appears that he merely notices their existence without mentioning any particular instance, and Hey's cases cannot be admitted as belonging to this class. Hewett states that "these sacs have been found in the three most common forms of *hernia*; but it is in the umbilical *hernia* they have been generally observed; the relative situation of the intestine and the *omentum* in the abdominal cavity will easily explain the fact. Complete omental sacs were found in four cases out of thirty-four operations for strangulated *hernia*, performed at St. George's Hospital in 1842–43; of these four cases two were femoral, one inguinal, and one umbilical. The formation of these sacs is attributed by Richter to the firm agglutination of the margins of the *omentum* which has surrounded the bowel. In this explanation of Richter's, which does not appear to be applicable to the majority of cases, the two following explanations of the manner in which these sacs are in some cases formed have been added:—*First*, the gut, *completely enveloped* by the *omentum*, passes through the ring, and the *omentum* thus disposed round the intestine becomes attached to the circumference of the neck of the hernial sac; this omental pouch is subsequently distended by the intestine, and thus forms a complete lining to the hernial sac. *Second*, an *epiplocele* takes place, and the portion of *omentum* which is protruded becomes altered in structure, and its folds firmly united to each other by the effusion of lymph; but within the abdominal cavity, in the neighbourhood of the ring, the fold, into which the *omentum* has been drawn may not be agglutinated; they will thus leave spaces into which a knuckle of intestine may insinuate itself, pass through the rings and form for itself a bed in the altered mass of *omentum* which is in the hernial sac. It may happen that two or three portions of gut may slip into the different spaces left between the folds of the *omentum*, and subsequently form for themselves separate pouches. Several separate sacs, with narrow necks, may be thus found in the omental mass, which is in the hernial sac. Once formed, these sacs may attain an immense size. In one case the sac measured six inches in length, and eleven inches in circumference at its broadest part. The *omentum* in which a sac has been formed, may in the course of time, especially if it is irreducible, become altered in structure, either by the effusion of lymph or by a deposition of fat, which takes place in the walls of the sac. By this alteration of structure the thickened sac may, in an operation, become the source of very great difficulties. * * * These omental sacs may either lie loose in the cavity of the hernial sac, or the two sacs may have contracted more or less extensive and firm adhesions with each other. (p. 284–87.) The neck of an omental sac may become the *sole* cause of strangulation, of which an instance is given. "The division of the neck of these omental sacs may be followed by hæmorrhage," of which he also mentions a case; the external bleeding at the operation was slight, and soon ceased; but after death a large patch of recently effused blood was found in the folds of the *omentum* near the mouth of the sac. (pp. 291, 92.)]

(a) Cooper's Hernia, above cited.

(b) Above cited.

(c) Observations on the Omental Sacs which are sometimes found in Strangulated Herniæ completely enveloping the intestine; in Med.-Chir. Trans. vol. xxvii. 1844.

(3) If the blood have not coagulated in the vessels of the *omentum*, cutting it off and tying them singly is not only an almost interminable business, but also when apparently all the vessels have been secured, and the patient put to bed, after a few hours secondary bleeding occurs from some little vessel or vessels which had escaped notice, the sac and yielding skin become largely distended with blood, in such quantity as to produce faintness, and require the reopening of the wound to remove the blood and tie the bleeding vessels. This disturbance of the wound prevents the adhesive process, and very commonly gives rise to abscess in the sac or its immediate neighbourhood, by which the cure is much retarded. A case of this kind occurred to me, and a large abscess was the result, although the patient ultimately recovered. It is on this account I prefer tearing through the *omentum* as much as possible, by which the ends of the vessels are ensheathed in cellular tissue, and do not bleed, or even tying up the *omentum* together.

The occurrence of abscess in the sac, independent of bleeding, and which sometimes reproduces symptoms of strangulation, has been noticed by Key, as will be presently seen (p. 49); first, in a case which occurred at St. Thomas's Hospital in 1817, which I remember to have noted; and secondly, in a case of his own.—J. F. S.]

1179. If the intestine have a dark, violet, even dusky colour, and its warmth be diminished, these must not prevent its reduction; only, according to some, the precaution should be taken of drawing a loop through the mesentery, for the purpose of keeping the returned intestine in the neighbourhood of the abdominal ring, and to afford a more free escape to the stool, if a part of the returned intestine be destroyed by gangrene.

[It not unfrequently happens, that though an intestine be a dark-chocolate colour when the sac is first opened, yet immediately after the division of the stricture, the colour, which has depended only on venous congestion, begins to alter, and the gut becomes florid. This is always a very encouraging sign.—J. F. S.]

1180. If the gangrene be more severe, which is characterized by loss of gloss, by an ashy-gray colour, by a softened condition, by the easy peeling off of the outer membrane of the intestine, if the gangrenous portion be but small, it must be opened with a lancet, and the gangrenous part fastened in a corresponding position to the abdominal ring. If a loop of intestine be attacked with gangrene, and the continuity of the intestinal canal destroyed, the gangrenous part must simply be cut off with scissors, as by the previous inflammation, adhesion of the rest of the intestine with the hernial sac has been effected, which prevents all effusion of stool into the belly. If the excrement will not escape of itself, an elastic sound must be introduced. The enlargement of the mouth of the sac with the knife is dangerous, as the division easily overshoots the boundary of the adhesion and may cause effusion into the belly.

Stitching up the intestine after cutting off the gangrenous part, as proposed and performed in various ways, is objectionable, as the stitch not holding the inflamed intestinal membranes, produces extension of the inflammation and gangrene.

1181. If in the protruded bowel any wounding substance be found, it must be removed by the wound; if the intestine be so narrowed and degenerated that it can no longer allow the passage of the stools, that part must be cut off, the wound brought together, by means of Lembert's stitch; or the intestine must be fixed in the abdominal ring, by a twist of the mesentery. In very small wounds only of the intestines, may the little opening be tied up with a silk thread (A. Cooper.)

1182. If in an old and bulky rupture, it be certain that it is not possible to return the contained parts, on account of the great adhesion and degeneration, the hernial sac must merely be laid bare at the abdominal ring, the strangulation relieved, and the rupture left where it was (1).

That mode of operating in which the hernial sac is not to be at all opened, but only the abdominal ring dilated so as to return the hernial sac together with the intestine, is, in general, to be rejected, and the not opening of the sac to be most especially confined to those cases in which it is certain that in a recently produced or extraordinary large rupture, or in a rupture entirely adhering to the neck of the sac, the strangulation is seated in the abdominal ring. In most cases the connexion between the aponeurotic opening and the hernial sac is so firm that the blunt end of a knife cannot be inserted between them, especially if a truss have been already worn (2).

Although **Franco** and **Paré** had cut into the abdominal ring and did not open the hernial sac, except when reduction could not be effected, yet the practice was first generally recommended by **Petit**, in large and adherent ruptures; after him, by **Garengeot** and **Monro**, in recent and small ruptures, and more recently by **A. Cooper**; but especially by **Key** (*a*) and **Preiss** (*b*) has it been laid down, to a certain extent, as the proper practice (2). The advantages resulting therefrom, are diminution of the danger, as the hernial sac is not injured; as well as that by keeping the air from the cavity of the belly inflammation, in any injury of an artery effusion of blood into the belly, and also injuring and tearing the intestine in incipient gangrene, are prevented; and when it seems necessary, the opening of the hernial sac can always be made. These benefits are, however, sufficiently outweighed by the disadvantages, that without opening the sac no insight can be obtained of the state and condition of the parts, the tightness at the neck of the sac may be caused by the entanglement of the intestine and by the peculiar position of the *omentum*, and the operation, especially in stout persons, is very difficult, and therefore only to be confined to the above-mentioned cases. With this mode of treatment must be placed **Guérin**'s (*c*) subcutaneous incision of the abdominal ring, which he would employ in all ruptures with recent strangulation from the ring, where, however, no sloughy destruction of the loop of intestine is to be feared. In strangulation by the hernial sac it is not applicable.

[(1) When a *rupture is large and old*, Surgeons generally follow **Astley Cooper**'s recommendation, of dividing the stricture without opening the sac and leaving the protruded gut in the sac or not, as may be. For this he assigns the following reasons:—"*first*, in very large old *herniæ*, the cavity of the *abdomen* is so much diminished by the habitual loss of the protruded intestine and *omentum*, that it becomes scarcely able to receive them again; and if a reduction is attempted, the force necessary to effect it endangers the bursting of the intestine; *second*, a large surface of intestine is exposed and handled for so long a time, as to produce, even if it does not give way, the risk of an inflammation which will probably be attended with fatal consequences; *third*, if by great pains the intestine be returned, it is scarcely possible to keep it in the now over distended *abdomen*, so that the slightest cough, or effort of any kind, is sufficient to bring it again down into the sac, and thus induce a high and dangerous inflammation; *lastly*, when great adhesion occurs, so much time is necessarily required in performing the operation, to separate the united surfaces, that fears may be justly entertained of the patient not surviving the operation. * * * Hence, in these cases, I would advise only the division of the abdominal ring; or if the stricture is higher up, of the lower edge of the *transversalis* muscle; but the hernial sac should not be opened, unless the stricture is situated in the sac itself." His mode of performing the operation he thus describes:—"I made an incision three inches in length, immediately over the abdominal ring, exposing it with the knife, as well as the *fascia*, which it sends off. I then made a hole in the *fascia* large enough to introduce a director, which I thrust up behind the abdominal ring, between it and the hernial sac; and passing a curved probe-pointed bistoury upon it I divided the ring. I then introduced my finger, and feeling some resistance from the *transversalis*, I carried the bistoury upon the director up to it, and divided this also." (p. 63.) It is rather odd, in referring to **Cooper**'s first reason for following this practice, that the case on which the operation just described

(*a*) Memoir on the advantages and practicability of dividing the stricture in Strangulated Hernia on the outside of the sac. London, 1833.

(*b*) Würdigung des Bruchschnittes ohne Eröffnung des Bruchsackes. Wien, 1837.

(*c*) Gazette Médicale de Paris, 1841. No. 33.

was performed, "had existed from the patient's (aged fifty-four) earliest years," and that it "was of enormous size, reaching half-way to the knees," yet after the division of the stricture, "it went up with a gurgling noise, as soon as his hand was laid upon the tumour." And as regards the danger of exposing and handling for a long time a large surface of intestine, as laid down in his second reason for not opening the sac, the only case he refers to is CARPENTER'S, who says:—"It was the largest *hernia* I ever remember to have seen;" and, having opened the sac "a large quantity of intestine, with a small piece of *omentum* protruded;" but after dividing the stricture, the adhesions were so great, that he "judged it advisable not to attempt their separation. And from the size of the *hernia*, it was quite impossible to bring the integuments over the intestine, which was therefore left exposed to the air;" yet nothing untoward ensued; "the intestine soon began to granulate, and gradually shrunk within the wound," and the patient recovered. (p. 64.)

This is the operation on which ASTLEY COOPER lays so great stress, observing:— "I feel convinced that this operation will be gradually introduced into general practice when it has been fairly tried, and found, if performed early, to be free from danger, and attended with no unusual difficulty." (p. 64.)

"If we cannot accomplish our object in this manner," says LAWRENCE, "a small aperture may be made in the sac, near the ring, which will enable the Surgeon to introduce a curved director under the stricture; the knife carried along the groove, divides the tendon with ease. When the parts are thus set free, they should be returned into the belly by pressure on the swelling, if adhesions do not prevent this; at all events, they generally admit of being replaced in part." (p. 285.)

(2) I do not think it can be fairly stated from ASTLEY COOPER'S published statements, that he is in the generality of cases favourable to, or that he recommends the practice of dividing the stricture, in strangulated rupture external to the sac, but only lays it down as the *general rule* in large ruptures. It is quite true that in his great work on HERNIA, in the first part of the first edition, when treating of the operation for inguinal rupture, he says:—"An advantage is derived from dilating the stricture without cutting the sac itself, for there is no danger of injuring the intestine, &c." (p. 30); and in the second edition he speaks more at length on the subject thus:—"I have occasionally practised, and for some time recommended in my lectures the following mode of dividing the stricture without including the sac. The tendon of the external oblique having been divided a little above the external ring, the sac is gently drawn down, while the muscles are drawn up by an assistant. In this way the stricture is brought into view, and can be divided without risk, and without including the *peritoneum*." (p. 39); and he then enumerates the advantages from this practice, that there is no danger of wounding the intestine, and that if the epigastric artery is cut, as the *peritoneum* is undivided, the flow of blood would be immediately perceived, and then the vessel might be secured. But in neither edition of his Surgical Lectures, neither that in the Lancet of 1823-24, nor that edited by TYRRELL in 1827, does he allude to the division of the stricture without opening the sac, except in large ruptures. In both these editions of his Lectures he also expressly directs opening the sac and says in the one (*a*), after "feeling for the stricture, * * * you introduce the probe-pointed bistoury on the director or finger, and divide the stricture without cutting too much;" (p. 478.) and in the other (*b*), "having thus exposed the contents of the hernial sac, as far as the seat of stricture, the operator should insinuate the point of his finger or a director under the stricture, between the sac and its contents, at the upper part, carefully keeping the latter from turning over the finger or director. He should then pass the knife for dividing the stricture upon the finger or director, under the stricture, and by a gentle motion divide this stricture, &c." (pp. 44, 5.) I may also add that I have no remembrance of having seen him operate without opening the sac, in the many operations for strangulated rupture which I saw him perform in the Hospital during the first fourteen years of my professional life.

To KEY, however, must be justly ascribed the revival of PETIT'S operation, and of its more extensive application (*c*). His views with regard to its employment will be seen in the following observations upon fifteen fatal cases. "The majority of the cases," he says, "appeared to have died from peritoneal inflammation consequent upon the exposure of an inflamed or strangulated portion of bowel. I say exposure of the bowel; for it is, probably, not so much the wound in the peritoneal sac that disposes to inflammation, as placing the bowel under circumstances to which it has hitherto been unaccustomed. The sudden change of temperature to which it is submitted, the exposure to

---

(*c*) Memoir, above cited.

light, and to a current of air, cannot but have some influence upon the delicate circulation of the part, and be productive of some impression on the nerves of so susceptible a surface as that of a strangulated intestine. And if to these influences be added the handling which the gut usually experiences, the reaction that follows these agents, we must regard as a natural consequence and likely (as experience proves) to amount to excessive inflammation. In tracing the inflammation consequent upon an operation for *hernia*, it is found to spread from that portion of the bowel that has been strangulated over the peritoneal surface of the intestines, and not to have its origin from the incision in the sac, although two wounds are usually inflicted upon it, one for the purpose of exposing its contents, and another, higher up, to divide the stricture. The *peritoneum* about the seat of stricture exhibits fewer signs of acute inflammation than the investment of the bowels." (pp. 11, 12.) After giving an "outline of these cases," Key observes, "it is obvious that the attempt to relieve the stricture without exposing the contents of the sac, could not have been attended with any untoward consequences in any of the cases, with the exception of the two cases of gangrene, Nos. II. and XII.; and in these the symptoms denoting the approach or existence of *sphacelus*, were sufficiently marked to point out to the operator the necessary mode of proceeding. Some of the other cases, in all probability, would have been benefited had the sac been left entire." (p. 26.)

Lawrence does not agree with Key in "ascribing the unfavourable state of bowel which was found in so large a proportion of his thirteen cases, (the other two not having been operated on,) and which, I believe, will be met with in the majority of those who die after the operation, to the operation itself and its attendant circumstances, namely, exposure to air and light, change of temperature and handling. I think it rather owing to the pressure of the stricture, which affects the parts, not like the slight violence of the operation, for a few minutes only, but uninterruptedly for hours, and sometimes days, disturbing the circulation, making an impression on the intestine as if it had been tied with a string, and sometimes causing ulceration either of the internal tunics or of the bowel in its whole thickness. That inflammation excited by this kind of injury may cause death is clearly proved by Mr. Key's cases. * * * When we find the intestines at the time of the operation mortified, as in cases II. and XII., distended and discoloured, so that it could not be replaced, and required to be opened, as in case V., so altered that the operator would not venture to return it, as in cases III. and VII., the mischief is obviously independent of the operation, and its source is rendered unequivocal when we see the tube marked by the stricture, and mortified at the part thus impressed, as in case IX." (pp. 279, 80.)

From a very careful consideration of the circumstances attendant on strangulated rupture, and from observation of the appearance which the bowel too frequently exhibits, and the results which follow, I cannot but agree with Lawrence that the mischief is rather owing to the "pressure of the stricture," than with Key, that it is "consequent upon the exposure of an inflamed or strangulated portion of bowel." But I think it is impossible to doubt that an additional cause is to be found in the unwarrantably violent and repeated squeezing which the rupture suffers during the use of the *taxis*: so that one is only astonished that the gut is so rarely burst, and the patient destroyed in a few hours. And then, as Key has well expressed it, "an operation is often regarded as a forlorn hope, resorted to in the extremity of danger, when the injurious effects of delay and violence combine to preclude a chance of success. The effect of exposing a contused part is seen in a common bruise; if the soft parts are severely contused, the skin remaining entire, the inflammation that follows subsides without injuring the texture of the part But if a small wound accompanies the injury, the inflammation proves destructive in its effects; sloughing of the cellular membrane, with copious suppuration ensues, and the process of healing is tedious. Between a common contusion and an intestine, or *omentum* bruised by the *taxis*, there is a close analogy; a breach of texture, in the one case, leads to the same effects as exposure in the other. Inflammation is in both the result; and the vitality of the parts being impaired, disorganization in both cases follows as the consequence of inflammatory action. If the contusion be not accompanied by a breach of the surface, no harm is anticipated; and just so if the bruised contents of a *hernia* are returned without a wound of the peritoneal sac, and consequent exposure, inflammation, if it does come on, seldom proves severe, and still more rarely fatal." (pp. 58, 9.)

Admitting that "the condition of the bowel, that above all others renders it an imperative duty to open the sac, is that of gangrene," and stating that "it is a remark made by some Surgeons of experience that the intestine is occasionally found to be in a state of gangrene when no symptom had existed before the operation to raise a suspicion of mortification having taken place," Key observes, "it does not, however, appear, that any pains have been hitherto taken to form a correct *diagnosis* of the circumstances under which gangrene has actually taken place; nor am I prepared to say, that, in all cases, such a certainty of *diagnosis* is attainable; I think, however, that if the attention of the profession were more closely directed to the consideration of the condition preceding gangrene, a near approach might be made, sufficiently accurate to direct the Surgeon's practice in all cases." (pp. 103, 104.) I cannot agree with Key that "the ordinary characters of a completely sphacelated portion of bowel are distinct enough," for I am quite sure that I have seen them all existing more than once or twice without any gangrene, but simply depending on the unwarrantable violence used in attempting to return the rupture. But I do agree with him, that "it sometimes happens that no such change takes place in the swelling, and then the evidence of gangrene is much more equivocal." It is by no means infrequent to find an intestine mortified, although the time it has been strangulated is short, and not the slightest external sign leads to the presumption of its condition; as, on the contrary, it now and then happens that the exterior of the swelling is tender, inflamed, doughy, and crackling, from the causes I have just mentioned, and yet the intestine within be healthy, and the patient recover the operation. As regards the loss of elasticity in the swelling, I believe it a very uncertain sign; the intestine may be gangrenous, but the sac full of fluid, as is commonly the case under such circumstances, and then the elasticity remains. The only sign which I think can be relied on, though even that is doubtful, is when the gangrenous intestine has burst; then, indeed, although the redness, doughiness, and crackling still remain, the rounding of the swelling subsides, and when a little pressure is made on it a central hollow is produced, and a sense of yielding beneath, very different from the pitting caused by pressure on œdematous cellular tissue.

Key mentions a case which occurred to him, in which "a fetid smell, similar to that described by Sir A. Cooper, was perceptible in the progress of the operation, before the sac was opened." The patient had a femoral rupture, and "a fetid smell arose from the swelling as soon as the *fascia propria* was opened; it was a smell arising from a decomposed portion of bowel, and the transudation of its fæcal contents. The intestine proved to be quite gangrenous, being black, devoid of lustre, and lacerable. Such a *fœtor* might, I apprehend, be discovered in most cases of *sphacelus* before the sac is opened; its absence should be ascertained in every case in which the contents of a *hernia* are to be returned without opening the sac. Before disorganization of the coats of the intestine takes place, transudation of fluid or of fetid air is probably prevented. In incipient gangrene, therefore, it is not to be expected." (p. 109).

One instance of fetid smell before opening the sac occurred to me in the case of strangulated umbilical rupture, (No. X. in my Table,) which had been so for thirty hours; but on exposing the gut at the operation, part of it was quite natural, and part dark chocolate-coloured, but shiny, and did not seem to be mortified; after death, at forty-eight hours from the operation, it had a dirty clay-coloured appearance, very different from that when first exposed.

Admitting that the presence of the fetid smell is always indicative of gangrene, though it has been rarely observed, yet its absence is no certain sign of the healthy state of the intestine; and, therefore, some still more definite symptoms of this dangerous condition of the gut are requisite before it can be decided with certainty previous to opening the sac.

Lawrence adheres to the old practice of opening the sac and dividing the stricture from within; he says:—"The mode of proceeding thus recommended by Sir Astley Cooper, and executed by him with perfect facility," which is also fully confirmed by Key's practice and experience, "would be found difficult to those less intimately conversant with the anatomy of ruptures, and in some cases, probably impracticable. It is therefore fortunate that we cannot regard it as a matter of much consequence. When the hernial sac has been freely laid open, we cannot suppose that the additional division of its neck will much increase the chance of *peritonitis*. If the stricture be divided in a proper direction, the epigastric artery is not endangered. Nor can the intestine be wounded if due care is taken to protect it, by using a deeply-grooved director, or by carrying the curved knife along the finger. It may also be carefully held out of the way when the stricture is divided, either by the operator or assistant; or it may be covered at that time by the handle of a scalpel. Let me observe further, that the method of dividing the stricture on the outside of the sac does not necessarily secure the protruded parts from injury. In an attempt of this kind recorded by Pelletan(*a*), the intestine was wounded. The question of eligibility between the ordinary course of proceeding, and this modification must be determined, like all other practical matters, by experience. Unless unequivocal advantage should be found in the latter, I should

---

(*a*) Clinique Chirurgicale, vol. iii. p. 102.

not recommend its adoption, being unwilling to introduce without absolute necessity, a new difficulty into an operation, always requiring consideration and caution, and frequently attended with embarrassing circumstances." (p. 290.)

From my own personal experience of the division of the stricture external to the sac, I can say nothing, never having performed it. But I do not think so great advantage is gained by not opening the sac, as is stated. From all the cases I have observed, either in the practice of others or in my own, I do not think cutting through the hernial sac, and consequently opening the peritoneal cavity, so serious as generally considered. If inflammation of the *peritoneum* have not been previously set up, either by the rough usage of the rupture, or by the irritation which a long strangulated or gangrenous gut produces, I cannot understand why making a small opening into the peritoneal cavity should be more dreaded than the long slits, which are now made without compunction, for the removal of diseased ovaries, and so forth. There are, however, some conditions which even those who advise leaving the sac untouched, admit, require that it should be opened, namely, confinement of the protruded parts by entangling bands, or by adhesion to the sac itself, and a gangrenous condition of the bowel. Under all circumstances therefore I am still disposed to continue the practice of opening the sac, as I have hitherto done, believing it to be the most safe. I cannot conclude these observations without stating that I believe much of the fatality attendant on operations for strangulated ruptures, depends on the improper after-treatment. I well recollect the time when, as soon as the patient was put to bed, he was dosed with senna and salts, with the view of speedily procuring stools, and his already irritable bowels being thereby rendered still more irritable, he speedily sunk. Although this practice is probably less followed now than formerly, yet I am afraid there is still too great inclination to employ purgatives too early. For a few hours nothing more than a clyster should be given, and not even that, unless the patient be very uneasy in his bowels, and puffed up with wind. Not unfrequently they relieve themselves, and only after twelve or eighteen hours is it advisable to give medicine by the mouth, for the purpose of completely clearing the whole intestinal canal. And unless there be any special indication for calomel, I believe that castor oil is the best remedy of all.

Luke, who is a great advocate for Petit's operations, observes (*a*) that "the operation itself admits of a very brief general description. It consists of an incision of the integuments over the seat of the stricture, followed by a division of the subjacent cellular texture and *fascia*, to which succeeds the cautious division of the stricture itself; and afterwards the hernial contents are returned into the *abdomen*, as by the *taxis*, without exposure. In femoral and in umbilical *hernia*, for all practical purposes of the operation, the seat of stricture may be assumed to be at the respective abdominal apertures, although in the former *hernia* there is occasionally some light variation upon that point. * * * In inguinal *hernia* the seat of stricture is far more variable, and the range of its variation extends from the internal abdominal ring to the *scrotum* in the male; consequently, without some previous indication to guide the operator, the external incision may be made over one extremity of the range, when the stricture is far away at the other, and a fruitless search may be the probable result. * * * There are several ways of conducting the necessary examination to obtain the desired *diagnosis*, all of which depend for their success upon the stoppage of the communication of impulse from one part to another by the stricture. Thus, if the body of a hernial tumour be compressed by the hand, an impulse is communicated to all its parts below the seat of stricture; but if the neck of the *hernia* be grasped between the finger and thumb of the other hand, above the stricture, while such compression is made there will not be any impulse felt. When, in the commencement of the examination, the neck of the tumour is first grasped, we may be always assured, that if an impulse is felt on compression of the tumour itself, the seat of stricture is nearer to the *abdomen*; and by gradually withdrawing the finger and thumb in that direction, while renewed compression of the tumour is made, a point will be soon reached at which impulse ceases to be felt. The point at which impulse first ceases to be felt, is the seat of stricture. In like manner, if an impulse is not felt when the neck of the tumour is first grasped, we may be equally assured that the stricture is situated nearer to the body of the *hernia*; and, by a like gradual approximation to it with the finger and thumb, an impulse shortly commences to be felt. That point is the uppermost part of the strangulated contents, which implies that the stricture is immediately above it; and, on inquiry, it will be found to correspond with the indications of an examination commenced from below, as just mentioned; and thus the two modes of examination will tend to the correction of errors, to which each separately is liable. The same information may be obtained by attending to the point of cessation of impulse when

(*a*) Operation for Strangulated Hernia; in Med. Gazette, vol. i. 1839–40.

the patient coughs; but this method is irksome and painful under circumstances of acute peritoneal inflammation, and on that account is not so generally desirable as that detailed. Yet much valuable information, not otherwise attainable, may be afforded by using this method in conjunction with that furnished by compression of the tumour. In some cases the stricture occupies a considerable portion of the neck of the *hernia*, but in most it is confined to a limited space. In the former case, before performing PETIT's operation, it is desirable to be acquainted with those limits, in order that, when extensive, suitable provision may be made for its complete division. The combination of the two examinations has this knowledge for its object, which is easily attained by attending to the points of cessation of impulse. The point of cessation of impulse on coughing indicates the upper boundary of the stricture, and the point of cessation of impulse on compression of the *hernia*, indicates its lower boundary of the stricture; and, consequently, the boundaries are the limits of its extent." (pp. 865, 66.)

He further observes: - "The probability of the necessity to open the sac to effect a return, is much increased when the stricture is caused by its thick and indurated neck. * * * When the stricture is situated exteriorly to the sac, a director may generally be easily introduced under it, and it may be as easily divided with a bistoury; but when the neck of the sac itself forms the stricture, no such measure can be adopted. In such cases its division should be accomplished by cutting the indurated and thick substance on its exterior surface only, taking the greatest care that the knife does not penetrate to the interior of the sac. If this step has been properly performed, the division is only partial, and little amount of relief will ensue. To render the relief effective, the partial division of the indurated neck should be repeated in one or two other situations on the circumference of the stricture, by which, at length, the stricturing substance is so far weakened in its power of resistance, especially when unsupported by surrounding structures, that it becomes susceptible of dilatation by the very moderate interior pressure of the hernial contents during the efforts of the *taxis*. Success does not frequently attend the first efforts, so that renewed partial divisions, and renewed efforts, are mostly required; and, however unpromising such cases may be, experience enables me to state, that in this way they often admit of relief without the necessity of opening the sac. The proportion of failures in the attempt is, from its nature, greater than that which is experienced in *herniæ*, strictured by the margins of the abdominal apertures; yet, inclusive of these failures, I have not any reason to consider their general amount large, having sustained only five failures out of thirty-two cases, on which I have attempted to leave the sac unopened." (p. 866.)

There is much good in the preceding observations, on which account I have so largely quoted them; but the success resulting from this practice, so very far beyond what usually happens in cases of strangulated rupture, leads to the suspicion that some of the number mentioned, might, perhaps, have been relieved without other operation than the *taxis*.—J. F. S.]

1183. When the intestine has been properly returned into the belly, and the wound and surrounding parts cleaned, the edges of the wound must be brought together either with sticking plaster or with a stitch, covered with wadding, and a compress, and this dressing bound on with a suitable bandage. The patient should be put in such position that the belly shall be relaxed, with his chest raised, and his thighs drawn up; he must observe the strictest quiet, and take only mild mucilaginous drinks. In general some hours after the operation the bowels are relieved of themselves; but if this do not happen, an oily mixture may be given, castor oil, clysters, calomel, and if no inflammatory symptoms exist, an oily mixture, with common salt. The dressing must be replaced as often as necessary, and a slight compression made opposite the abdominal ring. When the wound has scarred, a proper truss is to be applied. If inflammatory symptoms occur, they must be treated antiphlogistically. If there be inflammation, consequent on still existing strangulation, or if protrusion of the intestine again happen, and it be painful to the touch, the part must be returned into the belly by introducing the finger. If symptoms of strangulation still continue, on account of entanglement of the intestine within the belly, its adhesion or narrowing, the intestine must be protruded by coughing, or by introducing the finger. If the strangulation still continue several days after the operation, and the intestines be still protruded on account of adhesion, it may then be advisable, in complete obstruction of the intestine, to open it with a lancet.

Key (*a*) notices one circumstance in the after treatment, (especially in inguinal ruptures,) in which symptoms resembling those from strangulation occurred, viz., the transition of inflammation of the sac into suppuration. The *scrotum* swells up a day or two after the operation, becomes painful, hiccough and vomiting recur, the relief of the bowels is diminished or suppressed, and, from the fulness of the hernial sac, the patient has the sensation as if the rupture were again protruded. Distinct fluctuation is ordinarily not to be felt, on account of the thickening of the membranes. At first leeches and evaporating washes are to be applied, subsequently poultices, the closed wound is to be punctured with the lancet, and an escape made for the pus, *whereupon* the symptoms soon subside.

[I have had one case of suppuration of the sac of an inguinal rupture, but it did not cause any peculiar or dangerous symptoms, and after a few days emptied itself, and gave no further inconvenience.

I have once seen in a young man, operated on for scrotal rupture, and who was purged violently for some days, after taking five doses of two grains of calomel, with half a grain of opium every six hours, for *peritonitis*, inflammation extend from the sac up to the navel, and round into the right loin, which terminated in large sloughing of the cellular tissue; but he ultimately recovered.—J. F. S.]

1184. If the intestine be sloughy, it must be merely covered with a light compress dipped in a mucilaginous fluid. When all the slough is thrown off, and the artificial *anus* or fæcal fistula is formed by the union of the destroyed intestine with the neighbouring *peritoneum*, care is merely requisite for the due escape of the stools, the aperture is to be covered with wadding, and all pressure removed: the patient should take nourishing and easily digestible food; clysters and gentle purges should be often given.

[In general during the course of strangulation, the gut becomes so adherent to the mouth of the sac, that if it should mortify and burst, or if it be purposely opened by the Surgeon during the operation, it rarely recedes, and the stools, passing by the wound, form an artificial *anus*.

On the other hand an intestine may be returned into the belly, and slough afterwards. Key mentions a case (*b*) under Astley Cooper, in which strangulated inguinal rupture was operated on, "and the intestine, though dark-coloured, appearing to be merely congested, was returned into the *abdomen*. In the evening of the same day he passed stools *per anum*, and appeared relieved. On the third day, as soon as the poultice was removed, a quantity of fæculent matter was seen issuing from the opening; the discharge of *fæces* continued for five days, at the end of which time it altogether healed, and the wound speedily cicatrized." In another case, a strangulated congenital rupture, which occurred to Key himself; on the fourth day after the operation "a copious discharge of *fæces* had taken place at the wound. The *abdomen* had remained tender since the operation, but he had discharged *fæces per anum*. The discharge did not cease for several days, and delayed the healing of the wound. But at the end of about sixteen days, he became convalescent, and the wound entirely closed." (pp. 111, 13.) Lawrence mentions a remarkable case of bubonocele, which was operated on by Ramsden:—"The gut, which was much discoloured, was returned without difficulty, but seems not to have completely re-entered the abdominal cavity. On passing the finger as high as the incision would admit, if it did not fairly reach the *abdomen*, it seems as if the intestine, although free from stricture, were contained in a peculiar membranous bag." Clysters, which were ordered, could not be forced up, which led to examination of the *rectum*, and thence some hardened *fæces* were removed. She was much exhausted, but, by care, had considerably recovered next morning, and the bowels not having been moved, calomel and colocynth extract were given every two hours, which, in the evening, began to operate, and before morning she had eight or ten stools. She continued for a time in a very fluctuating state, but well-grounded hopes of her recovery were entertained till "she was seized, in about six weeks after the operation, with violent pain in the lower part of the *abdomen*, which terminated in two days in a discharge of *fæces* from the wound, and perfect ease. The appetite now failed, the strength decreased, and death took place on the tenth day from the appearance

---

(*a*) A. Cooper's Hernia, p. 58, *note*.

(*b*) Memoir

of *fæces* in the wound. On *examining* the body, the whole of the intestines were found so strongly adherent to each other, that they could not be separated without laceration. A portion of the *ileum*, the same, probably, which had been protruded, adhered to the abdominal ring. Its coats were greatly stretched, and its canal was much contracted. A small ulcerated aperture was discovered in this part; and led, in a fistulous form, through a substance nearly equal in size to the little finger, to the external wound." (p. 328.)

It has been well observed by KEY, that "cases are sometimes met with in which the patient appears to be doing well after the operation, the evacuations being free and natural, and the sickness and pain subsiding; but after the lapse of two or three days the powers begin to sink, the *abdomen*, though not very tense, is uneasy under pressure, the pulse small and quick, and the tongue becomes dry and coated. This condition is, perhaps, protracted for several days, and the patient at length dies. A *post mortem* inspection discovers the cause of death in the dark colour and lacerable condition of the strangulated portion of the bowel and the vascular state of the surrounding parts. This unexpected termination of a case, when it does occur, usually takes place in patients of enfeebled constitution, whose powers are unequal to the restoration of the healthy circulation in the strangulated bowel after its release from the stricture; and in whom, therefore, a slight degree of inflammation gradually ends in the extinction of its vitality. At the period of the operation the intestine, when exposed, presents none of the usual indications of present or approaching gangrene; no infiltration of its tissues, no discoloration beyond that which retarded circulation in a healthy bowel produces, no lack of peritoneal lustre, and no lacerability of texture; it in no point appears to differ from those cases of strangulation, in which an early operation is had recourse to before severe symptoms come on, and in which a favourable *prognosis* is verified by a rapid convalescence. Exposure

Tabular View of Operations

	Kind.	Sex.	Age.	Duration.	Truss.	Strangulation.	Vomiting.	Constipation.
1835. I. Aug. 17	Right scrotal, not small.	Male .	43	From childhood, but not congenital.	Worn for last seven years.	11½ hours	Seven hours, little.	Not mentioned how long.
1836. II. May 10	Left direct scrotal, (also on other side,) size of pigeon's egg.	Male .	73	15 years	. . .	3 days .	Constant . .	3 days . .
III. Oct. 29	Scrotal, large as child's head of two years	Male .	45	19 years . . .	. . .	12 hours .	Symptoms not urgent.	
1837. IV. Jan. 24	Scrotal, left, (also on other side,) size of an orange.	Male .	82	40 years, (incarcerated.)	. . .	4 days .	None . . .	4 days . .
V. Sept. 24	Femoral, right double sac.	Female	56	9 years	Four years cup-truss.	3 days .	Much . . .	3 days . .
1838. VI. Sept. 27]	Scrotal, right, as large as a pear.	Male .	46	2 years	For some time . (Symptoms of strangulation scarce, so that I did not operate for 24 hours.)	36 hours .	Slight . . .	24 hours naturally, but since by clyster.

---

* Upon these cases I operated in St. Thomas's Hospital during the first four and a half years of my quent severe illness has twice broken in on me, and prevented me keeping so regular an account since; from such tables.—J. F. S.

of a portion of bowel possessing such feeble powers of resistance to morbid influence cannot but tend to increase, probably to excite, a disposition to inflammation; which, though low in degree, is sufficient to destroy its vitality: and it may therefore be fairly regarded as the main agent in the production of gangrene." With this explanation I cannot agree; the mischief has been done to the bowel, or at least its foundation is laid, I believe, before the sac is opened, by the disturbance of the circulation during the strangulation, from which the bowel has not power to recover itself; and according as the stagnation of the blood has existed for a shorter or longer time, and to a less or greater extent, so does the mischief run on subsequently to inflammation and gangrene. —J. F. S.

"In cases in which great depression of the powers is observed to precede the operation," continues KEY, "death sometimes rapidly takes place without any other obvious cause than the exposure of the bowel. The condition of the patient is often found to be manifestly worse after the operation, and stimulants are obliged to be plentifully administered, in order to sustain the sinking powers of life. This may happen without inflammation of the abdominal cavity or gangrene of the bowel; and is attributable solely to the depressing effect of the operation. The pulse, which before the operation was feeble, becomes fluttering, and scarcely perceptible; the countenance, which was anxious, now bespeaks the approach of death; the skin is covered with a clammy moisture, and the whole frame is seized with a restlessness that gradually ends in the calmness of dissolution." (p. 51–4.)

ASTLEY COOPER mentions the very remarkable circumstance of *tetanus* following the operation for rupture, on the eighth day, by which the patient was speedily destroyed (*a*).]

(*a*) Above cited, p. 58.

*for Strangulated Rupture.**

Tenderness.	Contents.	Bowels moved.	Result.	Additional Remarks.
Of belly little, of rupture ditto.	Eight inches gut only, bright and turgid, thickened.	Freely within an hour.	Cured.	
Of belly much, with præcordial pain and hiccough from first day, which continued till third day after operation, and pain in belly ceased.	Sac divided by vertical *septum*, *omentum* before, gut behind; two inches gut, bright chocolate-coloured.	After 24 hours free motion from repeated clysters; the bowels continued to be moved, but though assisted with stimulants and nourishment, he gradually sunk.	Died on ninth day; intestine at mouth of sac still dark-coloured, little inflammation.	Large quantity of fat between cremaster and sac. I wounded intestine in opening sac with knife.
Of rupture, probably from attempts at reduction.	Half yard of intestine, front half of which chocolate and thickened, other unaltered, also large mass of *omentum*.	A slight motion from clysters after 24 hours, after same interval, and castor oil and clyster, bowels moved freely.	Cured (stricture not tight.)	Attempts were made to diminish size of rupture by application of ice, but without avail. The dresser had also given tartar emetic. The *omentum* was left. The gut came down again on ninth day, in getting out of bed, but slowly returned.
Of the rupture a little .	Much adhering *omentum*, almost schirrous, a small portion of *colon* healthy.	In eight hours after two clysters some *scybala* came away. Next morning he had calomel and castor oil, and the bowels were freely moved.	Cured (stricture none, but without dilating.)	Ice was applied for three hours before operation without benefit. Dilated the stricture and left the gut, but tore and cut off *omentum*. Probably in this case the *colon*, together with its peritoneal connexion to the iliac pit, descended, but I did not notice this at the operation.
Of the belly; has had hiccough throughout whole day; tenderness ceased on second day.	Bit of *omentum*, size of a walnut, in little sac; four inches choc. intest., shining, but slightly adherent, and much matted *omentum* in large sac.	An hour after, the bowels very freely opened, and again three hours after.	Cured (stricture not very tight.)	The larger piece of *omentum* was cut off.
None in belly nor in rupture.	Three inches chocolate, with a little patch of adhesive; no *omentum*.	Within eight hours after twice castor oil, very copious motions.	Cured (stricture very tight.)	Cremaster enormously thickened.

Assistant-Surgeonship; and it will be observed that for one whole year I had not a single case. Subse-
but I hope yet to resume and continue a similar one, as I am convinced of the advantage which accrues

	Kind.	Sex.	Age.	Duration.	Truss.	Strangulation.	Vomiting.	Constipation.
1838. VII. Nov. 4	Femoral, right, of large size and oblong form on POUPART's ligament, then bending down and extending into *labium*.	Female	55	10 years	Truss not fitting	10 hours.	Much throwing up of wind, but no vomiting.	36 hours . .
VIII. Nov. 28	Right scrotal, congenital; three fingers thick, one long.	Male .	22	Says he has only noticed the swelling 12 months.	Suspensory . .	12 hours.	Much . . .	24 hours . .
IX. Nov. 29	Femoral, (right,) not large, but flaccid.	Female	48	12 years	Six weeks . .	47 hours.	Much . . .	47 hours . .
1840. X. April 18	Femoral, (right,) swelling large.	Female	62	24 years	Partially irreduc.	23 hours.	Much . . .	36 hours . .
XI. June 15	Umbilical, (as large as a half-quartern loaf,) with cleft, so as to have hour-glass form.	Female	60	12 years	Partially irreduc., no truss.	30 hours.	Much, twelve hours.	36 hours . .
XII. July 4	Femoral, (right,) always small.	Female	57	20 years	No truss . . .	3 days .	Much, three days.	5 days . .
XIII. July 30	Scrotal, (left,) size of pigeon's egg.	Male .	60	14 years	Has worn . .	6 hours.	Much . . .	. . .
XIV. Aug. 16	Scrotal, (right,) also on left.	Male .	59	54 years on left, 18 on right after blow.	Has worn . .	26 hours.	Much . . .	36 hours . .
XV. Oct. 29	Femoral, (right,) size of pigeon's egg.	Female	45	20 years	Has worn till within last three years.	4 days .	36 hours, much	4 days . .

Tenderness.	Contents.	Bowels moved.	Result.	Additional Remarks.
At lower part of belly, near the swelling.	*Omentum* in *labium* soft, but in true sac firm and matted; in true sac knuckle of bright gut.	Within first nine hours the bowels thrice sparingly relieved by clyster. She went on very well, but the bowels were not satisfactorily moved till four days after the operation, although she had calomel and opium twice a-day, with occasional castor oil and senna and salts.	Cured, (stricture very tight.)	The inside of the sac had probably burst, and allowed the gut to escape into the *labium*.
Pain in belly, tenderness of rupture.	Two inches gut dark-coloured, bright.	Bowels moved by clyster and castor oil freely between 12 and 16 hours after operation.	Cured, (stricture at internal ring very tight, and like movable membranous ring.)	
A little pain in belly when pressed.	Healthy, bright, and dark coloured gut.	Nine hours after operation bowels freely moved by clyster.	Cured, (stricture tight.)	
Much pain in belly, and not relieved by the operation; no pain nor tenderness in swelling.	Much adhering *omentum*, four inches of intestine very dark, but shining.	A few *scybola* brought away by clyster 22 hours after operation, but nothing more.	Died 18 hours, (stricture very firm.)	Fetid smell on opening the sac. The adhering *omentum* was left alone. The vomiting continued after the operation almost to the last. On *examination*, the intestine gangrenous, with mark of separation; intestines slightly glued.
Swelling tender . . .	Sac divided by transverse band; hard mass of *omentum*, adherent in upper portion; eight inches of dark chocolate bright intestine.	Bowels relieved of thin motion 30 hours after operation, not without calomel and opium every two hours seven times; a single dose of calomel and clysters had previously been useless.	Died 48 hours, (stricture not tight.)	Fetid smell before opening the sac. A deep tough band of cellular tissue indented the hernial sac, which also had a corresponding deep fold. Vomiting continued till death. On examination, the intestine dirty clay-colour; no *peritonitis*.
Pain, but not tenderness, in the belly.	Very small knuckle of dark-coloured bright gut.	Three hours after operation a few small *scybola* after clyster, but after castor oil the bowels were freely moved during the day; purging came on on third day.	Died 65 hours, (stricture very tight.)	No account of examination.
Much pain in belly . .	Large knuckle of dark gut, very tense, and peritoneal coat seemed cracked.	Bowels twice moved within 12 hours by castor oil.	Cured, (stricture very tight.)	
Much pain in belly; after operation complained of pain about navel, which did not subside.	Half yard of gut, not deep-coloured, but much thickened and slightly ecchymosed.	Within 24 hours his bowels freely moved by clyster, after which they continued tolerably regular. Calomel and opium were given every six hours, and when his powers began to fail, brandy and arrow-root.	Died six days after, (stricture not tight, but required division, as also a band below it.)	The *scrotum* very large, much reddened, probably from efforts and crackling. Much difficulty in returning gut on account of its thickness. In course of the second day hiccough came on, and some sickness, which subsided, but came on next day, and frequently after to the last. Nor was it checked but slightly by hydrocyanic acid. On examination, all the intestines were found glued together; strangulated gut not restored, suppuration between cremaster and sac.
Much pain in belly, with tympany.	Mass of healthy *omentum* adherent, small bit of reddened but not dark gut, size of top of thumb.	The bowels were not moved till a few hours before death.	Died 36 hours, (stricture tight.)	She was, when first seen, very much depressed, and the surface cold. Three or four ounces of straw-coloured fluid escaped from the belly after reduction, immediately on the return of the gut. The *omentum* left in sac. Calomel and opium were ordered directly after the operation on account of the pain and tenderness of the belly. Egg and brandy, and other nourishment were given without avail. Slight *peritonitis*; only a portion of intestinal tube, size of sixpence, had been strangulated, and lay just above mouth of sac.

SECOND CHAPTER.—OF ABDOMINAL RUPTURES IN PARTICULAR.

I.—Of Inguinal Rupture.

Also the writers before mentioned.

1185. *Inguinal Rupture* passes through the *abdominal ring* (*annulus abdominalis*); it may be either *Scrotal*, (*Hernia scrotalis*, Lat.; *Hodensackbruch*, Germ.; *Oscheocele*, Fr.,) when descending into the *scrotum*, or *Labial*, (*Hernia labii pudendi externi*, Lat.; *Bruch der äusserer Schaamlippe*, Germ.; *Hernie des grandes lèvres*, Fr.,) when passing into the *labium*.

1186. The *front* or *outer abdominal ring* is the external opening of the *inguinal canal*, (*canalis inguinalis*,) and is formed by the tendon of the external oblique muscle stretching from the upper front spine of the hip-bone to the pubic *symphysis*, (Poupart's *ligament*, or the *external inguinal ligament* of Hesselbach,) where the fibres separating, attach themselves by one part (the *inner pillar of the ring*) to the pubic *sym-*

physis, and by the other (the *outer pillar of the ring*) to the spine of the share-bone. A triangular opening is thus formed, of which the share-bone is the base, and the point inclining upwards and outwards is the junction of the two pillars. By the splitting of the muscular fibres of the internal oblique abdominal muscle, the junction of its tendon with that of the transverse muscle, forms the other part of the inguinal canal. The internal opening of the inguinal canal (*hinder* or *inner abdominal ring*) is formed by an *aponeurosis*, (the *fascia transversalis* of COOPER, the *internal inguinal ligament* of HESSELBACH, *the external layer of the peritoneum* of LANGENBECK,) commencing from the hinder edge of POUPART's ligament, which seems to twist itself upwards and backwards. This *aponeurosis* loses itself above in the cellular tissue which overspreads the inner surface of the transverse muscle, and is continued to the under surface of the diaphragm. Internally it arises from the outer edge of the tendon of the straight muscle, which unites with it, and therefore at this part it is strongest. Where the strong fibres of this *aponeurosis* ascend obliquely outwards over the femoral vessels, they form an oblong aperture for the passage of the spermatic cord (which, according to CLOQUET, is covered by this *aponeurosis*, to the testicle, where it is connected to the vaginal tunic) (1). The inguinal canal is directed from without and above, inwards and downwards, as it passes from the hinder or inner to the front or outer ring, and is from one inch and a quarter, to an inch and a half long. Its front wall is formed by POUPART's ligament, and a small part of the internal oblique muscle; its hind wall inwards and upwards by the delicate fleshy bundles of that muscle, and below and without, by the *fascia transversalis*. In the male the spermatic cord passes through the inguinal canal, and is surrounded besides by the process of the transverse *fascia*, by cellular tissue, and covered by the cremaster muscle, (the lengthened fibres of the internal oblique muscle,) the general vaginal tunic, (*tunica vaginalis communis*, according to LANGENBECK,) a process of the external layer of the *peritoneum*. The external surface of the external oblique muscle is covered with a delicate aponeurotic expansion considered to be a process of the *m. fasciæ latæ femoris*, and which spreads over the front inguinal ring and the spermatic cord (*tunica dartos*, *fascia superficialis* of COOPER) (2). The epigastric artery arises from the external iliac above POUPART's ligament, ascends between the transversal *fascia* and the outer layer of the *peritoneum*, inwards and upwards, on the inside of the hinder or inner inguinal ring, there crosses the spermatic cord, reaches the edge of the straight muscle about an inch and a half from its origin, and runs upwards on its hind surface. If the region of the groin be examined on the peritoneal side, the trace of the obliterated vaginal tunic is seen at the point which corresponds to the hinder inguinal ring, and in many cases there is a depression in the *peritoneum*, which indicates the upper part of that tunic remaining open; on the inner side of this spot lies the epigastric artery. Between this and the umbilical artery, opposite the front or outer inguinal ring, is seen a slight depression, (inguinal pit, *fovea inguinalis* of HESSELBACH,) where the *peritoneum*, towards the external ring, is covered only by the weaker parts of the transversal *fascia*, and by the delicate bundles of the internal oblique muscle.

[(1) The description of that most important part in ruptures, both inguinal and femoral, namely, the *fascia transversalis*, is not given by CHELIUS so clearly as might be; for it is far less difficult either to dissect or describe than commonly considered. At the onset it must be remembered that it is not a tendinous, but merely a cellular membranous structure, much condensed, and connecting the whole hind surface of the abdominal muscles with the front of the *peritoneum*. It is not part nor process of Poupart's ligament, but simply attached to it by one of its processes, whilst the other descends behind it, the former commonly called the iliac, and the latter the pubic portion of the *fascia transversalis*. The iliac portion commences by a sharp angle at the outside of the pubic spine, and ascends outwards, closely attached to the back and upper edge of Poupart's ligament to the upper front spine of the hip-bone, gradually increasing in width, and having a scythe-like shape, with the edge upwards and inwards, to the middle of that ligament, where it suddenly spreads upwards and is interposed between the back of the abdominal muscles and the front of the *peritoneum*, and is said to be lost on the diaphragm, which, however, is not really the case, for it continues as the connector of the *peritoneum* with that muscle, and then descending upon the front of the loins connects it with the lumbar muscles, and runs down upon the *iliacus* muscle on either side, between them and the *peritoneum*, and having attained those regions assumes the name of *fascia iliaca*, where for the present it must be left. I have said that the iliac portion of the *fascia transversalis* was scythe-shaped to the middle of Poupart's ligament, and it is there, about an inch in depth. It then runs inwards and descends behind the lower part of the straight muscles, is fixed to the back of the pubic bones, as far as their spines, spreads out on either side beyond them, behind and connected but slightly with the scythe-like portion, up to the upper front spine of the hip-bone; this from its attachment is called the pubic portion of the *fascia transversalis*, and its shape is more sickle-like, with the concavity upwards and outwards. The sudden turning inwards and downwards, and afterwards outwards and upwards of the pubic portion unconnected, or but loosely connected with the iliac portion of the *fascia transversalis*, leaves a gap about an inch and a half above Poupart's ligament, the hinder or inner abdominal ring, which has a sort of oval shape, or rather like the periphery of the vertical section of a pear.

That part of the pubic portion from below the inner ring to the spine of the share-bone, and behind the scythe edge of the iliac portion of the *fascia transversalis*, alone forms the floor or back of the inguinal canal, down to the upper edge of the external ring, but between this and its connexion to the spine, and *symphysis* of the share-bone, it is strengthened by the lower ends of the conjoined tendons of the internal oblique and transverse muscles, which descend in front of and closely connected with it, to be fixed from the spine to the *symphysis* of the share-bone, and thus together they shut like a window-shutter against the back of the external ring. A little shallow triangular groove extends from the internal to the external ring formed by the scythe edge of the iliac portion in front, and the pubic portion of the *fascia transversalis* behind, and in this as in a gutter lies the spermatic cord or the round ligament.

It must not be supposed that the inner ring is an actual aperture, except during the descent of the testicle, and then indeed it is only the orifice of a cellular pouch thrust down below the pouch of the *peritoneum*, which subsequently forms the vaginal tunic of the testicle; and when, after the arrival of that organ in the *scrotum*, the *peritoneum* upon the cord gradually closes and thins, so likewise does the pouch of the *transversalis fascia*, forming the *fascia* of the cord, described by Astley Cooper long before Cloquet's account of it. In addition to this *fascia* from the inner ring a similar funnel of cellular tissue from the outer ring is given off as the cord passes through it, and the two *fasciæ* so called become confounded into one below, between the external ring and the testicle.

(2) The superficial *fascia* or *aponeurosis* of the external oblique muscle is not tendinous, but merely the cellular tissue which connects the skin with the front of the abdominal muscles, and descends upon the spermatic cord and testicle to connect them with the skin of the *scrotum*.—J. F. S.]

1187. At these two points inguinal ruptures are formed, and upon the difference in their origin depends their division into *external* and *internal*, or *oblique* and *direct* of English Surgeons.)

1188. *External or Oblique Inguinal Rupture* (*Hernia inguinalis externa*, Lat.; *Äussere Leistenbruch*, Germ.; *Hernie inguinale externe*, Fr.) commences at the seat of the obliterated canal of the vaginal tunic, or the intestines pass into the canal itself, which remains partially or completely open. This rupture proceeds from above and without, inwards and downwards, in the direction of the spermatic cord, as a cylindrical swelling; the spermatic cord lies on its inner hinder side, and the epigastric artery passes under the neck of the hernial sac and upon its inner side; if it be returned, a peculiar gurgling is heard.

1189. *Internal or Direct Inguinal Rupture* (*Hernia inguinalis interna*, Lat.; *Innere Leistenbruch*, Germ.; *Hernie inguinale interne*, Fr.; *Ventro-inguinal Hernia* of COOPER) passes out of the inguinal pit directly from within outwards through the external inguinal ring; it has a peculiar rounding, a short neck; it raises the inner pillar of the abdominal ring considerably; the spermatic cord lies on the outer side of the swelling; no gurgling is heard on its return.

1190. The symptoms by which external and internal inguinal ruptures are distinguished from each other, are only certain at the commencement of their existence, and whilst they have yet no great size. When the external inguinal rupture has become very large, it completely loses its cylindrical form, its oblique narrow neck, and passes directly out of the cavity of the belly. The position of the spermatic cord in old ruptures is equally various; not unfrequently are the vessels separated from each other by the pressure of the swelling.

1191. External or oblique inguinal rupture passes through the hinder (inner) inguinal ring into the general vaginal tunic, and may descend to the testicle, the proper vaginal tunic of which it touches. Its own coverings therefore are, 1, the skin of the *scrotum*; 2, the *fascia superficialis*; 3, the *tunica vaginalis communis*, upon the upper surface of which spread the fibres of the cremaster muscle; 4, the hernial sac itself, an unnatural lengthening of the *peritoneum*, covered on its outer surface with loose cellular tissue. In old ruptures these layers are often of considerable thickness.

Sometimes the external inguinal rupture does not pass through the front inguinal ring, but remains lying in the inguinal canal; it is then called *imperfectly developed inguinal rupture* (*Rupture in the inguinal canal* of English Surgeons.) It forms in (above) the middle of POUPART's ligament, above (before) the crural artery, a round or obliquely oval swelling, which becomes larger by coughing, is accompanied with an unpleasant sensation of pressure and dragging, and easily thrust back on application of the finger. The external inguinal ring is free. If the rupture increase, it descends obliquely inwards and downwards, towards the external inguinal ring, and passes through it. But it often exists as an undeveloped inguinal rupture, and spreads upwards and outwards. Besides the coverings already mentioned, this is covered with the front wall of the inguinal canal; to wit, the tendon of the external oblique, and the muscular fibres of the internal oblique muscle (1).

[(1) It is not covered by the muscular fibres of the internal oblique, for as soon as the rupture is formed by protruding through the upper or internal abdominal ring, the muscular edge of the internal oblique and transverse muscles slips back, and rests upon the upper and back part of the swelling.—J. F. S.]

1192. The internal or direct inguinal rupture projects at the inguinal pit, either between the fibres of the *fascia transversalis*, and the thin bundles of the internal oblique abdominal muscle, or protrudes with it the *fascia transversalis*; it drives down external to the vaginal tunic into the *scrotum*, and if it sink lower than the spermatic cord, the testicle rests upon the fore or outer part of the body of the hernial sac. The coverings of this rupture are, 1, the skin of the *scrotum ;* 2, the superficial *fascia ;* 3, sometimes some bundles of the cremaster muscle (*a*) ; 4, sometimes the transverse *fascia* (*b*) ; 5, the hernial sac, with its external surface covered with loose cellular tissue.

(*a*) As long as internal inguinal rupture is not far from the abdominal ring, it is not covered with the cremaster ; but in great protrusion it can incline farther outwards, and then it is possible that some fibres of the cremaster may appear on it, beneath which it simultaneously slips down.

(*b*) This usually appears to be the case, and the cause why the internal inguinal rupture can never attain the size of the external.

1193. It must be considered as a strong disposition for inguinal rupture if there be only a partial remaining open of the upper part of the vaginal canal for the outer, and a great elevation of the duplicature of the *peritoneum,* in which the umbilical artery lies, for the inner inguinal rupture.

1194. The *ileum* is the most common intestine in inguinal rupture, next it the *cæcum* and its wormlike process. If the *cæcum* or *colon* protrude, the ligaments are lengthened which connect them to the *peritoneum,* and also that part of the *peritoneum* which is connected with the intestines is drawn down, so that between the hernial sac and the intestines there is the same natural connexion as existed in its previous position. In these ruptures of the *cæcum* and *colon,* part lies externally to the sac, as in the belly it had lain external to the *peritoneum.* In general the hinder or under part of its calibre is protruded ; as it drops down however the intestine often twists, so that its bare part lies in front, in which case the rupture seems to have no hernial sac. The *omentum* commonly passes into an inguinal rupture, especially on the left side. With the internal inguinal rupture a portion of the urinary bladder sometimes protrudes, which cannot be drawn from the sac. In rare cases, in women, the internal generative organs are contained in inguinal rupture. Inguinal ruptures are much more frequent in men than in women. The frequency of internal to external inguinal ruptures is as one to fifteen.

1195. If the intestine pass *into the still open canal of the vaginal tunic* of the testicle, it is called a *Congenital Inguinal Rupture* (*Hernia inguinalis congenita seu processus vaginalis,* Lat. ; *angeborner Leistenbruch,* Germ. ; *Hernie inguinale congénitale,* Fr.) The origin of congenital inguinal rupture depends, in addition to the vaginal tunic remaining open, upon special causes :—*first,* on the long continuance of the testicle in the external inguinal ring, because then the vaginal canal has less disposition to be obliterated ; *second,* after birth the protrusion is always favoured by respiration and by the action of the abdominal muscles ; *third,* by adhesion of the testicle with the *omentum,* or with the intestine, previous to its descent, or if the intestine be connected with the *peritoneum,* as the *cæcum* on the right side, it may be drawn down with it.

1196. Congenital inguinal rupture has the same relations as external or oblique inguinal rupture, but is distinguished by the following circumstances, *first,* the common external inguinal rupture does not descend over the place where the general vaginal tunic is connected with the testicle ; in congenital rupture the intestines touch the testicle, and can thrust it upwards and backwards ; *second,* congenital rupture develops itself more as the hernial sac is not formed by the early gradual elongation of the *peritoneum.*

1197. The coverings of congenital inguinal, are the same as those of external or oblique inguinal rupture, except that the hernial sac is formed by the *tunica vaginalis propria*. In rare cases a second lengthening of the *peritoneum* may descend into the still open canal of the vaginal tunic, by which the intestines descending into this sac are separated from the testicle (*a*). The congenital inguinal rupture is mostly intestinal, because the *omentum* is very short; it may however contain a portion of *omentum* if it have been adherent to the testicle in the belly (1).

Narrowing of the hernial sac occurs most frequently in congenital inguinal ruptures, and consequently often several nearly perfectly closed hernial sacs are formed (*b*).

[(1) This is Astley Cooper's *Encysted Hernia of the Tunica Vaginalis*, in which "on opening the *tunica vaginalis*, instead of the intestine being found lying in contact with the testicle, a second bag or sac is seen enclosed in the *tunica vaginalis*, and enveloping the intestine. This bag is attached to the orifice of the *tunica vaginalis*, and descends from thence into its cavity; it generally contracts a few adhesions to the *tunica vaginalis*, whilst its interior bears the character of a common hernial sac." Cooper considers that in this case "the *tunica vaginalis*, after the descent of the testicle, becomes closed opposite the abdominal ring, but remains open above and below it. The intestine descends into the upper part, and elongates both the adhesion and *tunica vaginalis*, so as to form it into a bag, which, descending into the *tunica vaginalis* below the adhesion, and becoming narrow at its neck, though wide at its *fundus*, receives a portion of intestine. * * * The disease does not appear like *hernia* of the *tunica vaginalis*, as the *testis* is not involved in it, but can be distinctly perceived below it. * * * The strangulation arises from the contracted state of the mouth of the hernial sac." (p. 79-80.)].

1198. Various swellings which occur in the inguinal region must be distinguished from ruptures; such are *hydrocele*, *varicocele*, *inflammatory swelling of the spermatic cord*, *arrest of the testicle at the abdominal ring*, *collections of fat in the cellular tissue of the spermatic cord*, *collection of pus*.

1199. It is hardly possible to mistake a collection of water in the *tunica vaginalis propria* for a rupture. If the *hydrocele* be large, it may extend up to the abdominal ring and seem to penetrate within it, but if the swelling be drawn a little down, it will be seen that it does not lie in it, and that the ring is in its natural condition. In *hydrocele* the swelling ascends gradually towards the abdominal ring. The functions of the intestinal canal are undisturbed; lying on the back and coughing have no effect on the swelling. Congenital *hydrocele*, where indeed water is collected in the canal of the vaginal tunic, has greater resemblance to rupture; however, the consistence of the swelling, its transparency, its more easy or more difficult reduction, its quicker or slower reprotrusion, give the explanation (1). The diffused collection of water in the cellular tissue of the spermatic cord (*Hydrocele tunicæ vaginalis communis*) has the greatest resemblance to an omental rupture. The swelling which originates along the spermatic cord is broader below than above, seems to diminish on slight pressure, though it recurs immediately the pressure is withdrawn on lying down and standing up. If there be fluctuation, it is only at the bottom; if the bottom of the swelling be pressed, the fluid gently rises towards the apex, and expands it. If the swelling be within the abdominal ring, it stretches it; the patient often feels a pain at some part, and a dragging in the loins. As a distinctive character from omental rupture, it must be remembered that *hydrocele* of the cord has less con-

sistence and a less irregular surface than omental rupture; it is also usually somewhat broader at the base, whilst in omental rupture the contrary occurs (*a*).

[(1) Although hydrocele of the common kind, namely, that in the vaginal covering of the testicle itself, cannot, without great carelessness, be mistaken for scrotal rupture, as its slow formation, its commencement from below instead of above, and its transparency sufficiently characterize it; yet if the hydrocele be situated in the cord itself, it may, at first sight, be thought to be a hernial swelling, especially as it seems to begin at the top instead of the bottom of the *scrotum*, and the patient's account of its origin is often very confused. I have seen three or four cases of this kind, and the last which I had under my care presents a very good example of the usual occurrences in this complaint.

Case.—W. H., aged thirty-five, a healthy carpenter, was admitted

May 30th, 1845, and says, he had never any swelling in his groin till three weeks since, when, as he was lifting a heavy weight, he suddenly felt something snap in the left groin; but he suffered neither pain nor uneasiness, and continued his work during the rest of the day, without further noticing it. On rising next morning, however, he observed a small tumour, about the size of a filbert, in the left groin, which he says entirely disappeared when he was lying down on his back, and was capable of reduction when he stood upright. He was told the swelling was a rupture, and advised to wear a truss, for which he applied to a maker, who being unable to return the swelling, applied the truss upon it five days ago; from which to the present time he has continued to wear it, but the swelling increasing in size and becoming painful, he applied to a practitioner, who considering the disease to be an irreducible rupture, sent him to the hospital. The swelling was in the course of the left spermatic cord, about the size of a hen's egg, and extended up to the external ring and down to the testicle; above it the cord could be grasped, the finger and thumb almost meeting; it was firm and elastic; very tender to the touch (probably from the irritation of the truss); and a portion of it about the size of a walnut, was transparent. From these circumstances I was led to believe it a hydrocele of the spermatic cord. Some, however, might suppose, as it arose so suddenly, that the swelling was caused by tearing of one or more lymphatic vessels whilst he was exerting himself. Nothing further was done than applying hot flannels to the swelling, keeping him in bed, and giving him a dose of opening medicine. In the course of six days it had diminished to the size of a nut, and at the end of a fortnight had entirely disappeared.

A boy, aged six years, was brought to the hospital

May 5, 1838, considered to have strangulated rupture. He has worn a truss for several years. His bowels have not been moved for the last three days, and he has vomited several times, but not since yesterday morning; neither has medicine, which he then took, been rejected, although it has not operated. The right side of the *scrotum*, as far as the *raphe*, is distended with fluid, semi-transparent and œdematous; its shape flat, and much the form of the testicle; it is firm, but indents on pressure of the fingers, and reaches up to the abdominal ring, where it narrows. I could not satisfy myself as to the existence of any rupture, but thought it had the appearance resembling what I should suppose a burst hydrocele might assume. His mother took him away, promising to bring him back; but he never returned.

Very recently a similar case to the first was received into the hospital, and as in it, the cord could be grasped between the swelling and the external ring; but some doubt of its nature being entertained, a cut was made into it, some straw-coloured serum escaped, and the cyst found to be closed and quite free from the belly.

Sometimes these hydroceles of the cord may result from the patient having worn a truss sufficiently long to produce adhesion of the mouth of the sac and shut off the lower part from the belly without its cavity being obliterated. Sometimes after the adhesion of the mouth of the sac, it may be again thrust down, either partially along the cord, in which case there may be a collection of water in the old sac, between the new one and the testicle; or the newly protruded sac may descend before the vaginal covering of the testicle, and carrying down with it the old sac, the latter may become situated between the new sac and the vaginal coat of the testicle. This appears to me to be the case in two preparations in the rich collection of ruptures at St. Bartholomew's Museum; and these cases are further interesting, as both also have hydrocele of the vaginal coat of the testicle itself.

(*a*) SCARPA, Sull' Ernie, Memorie Anatomico-chirurgiche. Milan, 1809. fol.—IB., A Treatise, on Hernia, translated; with Notes by WISHART. Edinburgh, 1814. 8vo. p. 97.

Sometimes a rupture is accompanied with a common hydrocele below it; but in more rare cases the hydrocele is in front of the rupture, and generally is not discovered till the operation is performed, when it is liable to produce confusion, and make the operator suppose he has mistaken the case.

Thomas Blizard appears to have been the first person who observed hydrocele in front of an inguinal rupture. His patient had been subject to bubonocele on the right side upwards of six years, and he had almost constantly worn a truss. During the last two years of this period, a swelling of the testicle on the same side, which seems to have been hydrocele, occurred, but after a few months disappeared, and left the testicle wasted and drawn up to the groin. "When first called to him," says Blizard (a), "I found a small bubonocele on the right side, and could distinctly feel the *testis* of the same side, but very small, lying at the bottom of the *hernia*, having an inclination forwards. * * * Twenty hours after the descent I performed the operation. Having dissected down to a membrane, which I considered to be the hernial sac, I punctured it at the upper part, and then laid it open its whole length. It extended within the ring, which to obtain room for examination, I dilated. Upon further inquiry, I found the *hernia* was situated more deeply, and that the membrane which I had laid open was the *tunica vaginalis testis*, extended by the hydrocele, which had entirely disappeared. I then of course dissected through this *tunica vaginalis* at the posterior part, and laid open the hernial sac, which contained a portion of intestine nearly black from strangulation." The stricture was at the mouth of the sac. "In this case the *hernia* must have been behind the cord." (p. 66.)

Another example of this kind occurred to the younger Cline shortly after, and is mentioned by Astley Cooper (b). I witnessed this operation. "On making an incision. into that which was supposed to be the hernial sac, a fluid similar to that of hydrocele escaped, which it afterwards proved to be, for it was the *tunica vaginalis* which had been opened; on dilating this opening a little, a tumour presented itself, which was afterwards found to be from $\frac{1}{8}$th to $\frac{1}{4}$th of an inch thick, which, being dissected through, a fluid resembling the first in colour, but of a fetid smell, came out. This tumour was found to be the *tunica vaginalis* of the cord, but much altered from the natural appearance by a quantity of lymph that had been effused, which gave it the appearance of India rubber; the intestine had adhered firmly to the adjacent parts, and the stricture was divided with (on) the finger. Mr. Cline thought it not advisable to attempt to break through the adhesions, so as to return the intestine, lest it might bring on a dangerous degree of inflammation." (p. 17.) He did well. These cases are not so uncommon as formerly supposed, and many of our Museums in London possess two or more examples.—J. F. S.]

1200. *Varicocele*, when it has attained considerable size, has indeed some resemblance to omental rupture, the abdominal ring is not, however, stretched; the several strings of the swollen vessels are felt; if the swelling be compressed for a few moments between the fingers, without thrusting it back towards the belly, it almost entirely disappears; the whole mass of the testicle seems expanded into varicose vessels. In doubtful cases, let the patient be laid on his back, return the swelling, and press with the finger on the abdominal ring; this pressure will, when he rises, be sufficient to prevent the protrusion of the intestine, but not to suppress the flow of blood into the spermatic vessels.

1201. If an inflammatory swelling of the spermatic cord be developed spontaneously, the *diagnosis* is doubtful, so much the more, if injuries, as violent strains, blows, and the like, which equally cause ruptures, produce this inflammation. Such inflammatory swelling passes through the abdominal ring, descends to the testicle, which seems as it were confused with the swelling; it is elastic, painful, and manifestly inclosed by the inguinal canal. Fever comes on, the bowels may be drawn in to participate, suppression of their relief, disposition to vomiting and the like are produced. In such cases the *diagnosis* is more difficult, if previously there were a rupture which has become strangulated by the injury which has excited the inflammation of the cord.

(a) Astley Cooper, above cited.

(b) Above cited.

1202. When the testicle only, at a late period, descends through the inguinal canal, or when, on account of the shortness of the spermatic cord, it remains in the canal, it may by the opposition which the walls of the canal offer it, become inflamed. If in examining the *scrotum*, only one testicle be found, the *diagnosis* is thereby determined. An imperfectly developed external inguinal rupture may exist at the same time with one testicle lying in the groin, the protrusion of which may cause the severest pain, by its pressure on the testicle, as I myself have noticed in one instance.

[(Key (*a*) mentions a case of strangulated inguinal rupture, in which the testicle had never descended lower than the external ring, in consequence of which "the shape of the swelling was peculiar; the *hernia*, instead of passing downward into the *scrotum*, turned, after emerging from the inguinal canal, over the tendon of the external oblique muscle, and appeared somewhat like a femoral *hernia*." (p. 25.)

There is also an example of this kind in the Museum of the Royal College of Surgeons; and at St. Bartholomew's there is an instance of a congenital rupture in the inguinal canal, in which the testicle also is still remaining.—J. F. S.]

1203. Fat may be collected in the cellular tissue of the spermatic cord, project from the abdominal ring, or may exist along the cord in the *scrotum*, and form a swelling, which otherwise is accompanied with scarcely any inconvenience. But a collection of fat may arise upon the front or hind surface of the *peritoneum*; in this enlargement the fat descends through the abdominal ring into the *scrotum*, and drags the *peritoneum* with it. These so-called *Fat-Ruptures*, which may be formed on different parts of the belly, have the greatest resemblance to omental ruptures, especially if they, as is frequently the case, can be reduced.

Collections of fat upon the surface of the *peritoneum* may protrude through the white line, through the interspaces of the muscles, or through the natural apertures of the belly. If these swellings be situated at or upon the white line, they rarely attain any considerable size; usually their size is from that of a nut to that of an egg. Some fatty granules, deposited on the outer surface of the *peritoneum*, are gradually received into one of the little openings or clefts formed by the fibres of the tendinous *aponeurosis*, where they by degrees grow and enlarge, become converted into a swelling with a neck, the root of which is attached to the *peritoneum*, the neck surrounded by the fibres of the *aponeurosis*, and the bottom spread beneath the skin. They are usually firmer when small, and penetrating through a small opening; on the contrary, of looser texture when large, and increasing without restraint. Often they seem to be reduced and got rid of, but often they are immovable. The continual dragging to which they are subject not unfrequently produces a funnel-shaped projection of the *peritoneum* at that part where they arise, and thus they present a sac-like extension, surrounded by a fatty swelling, which, according to Velpeau, may cause a real rupture; this danger, however, Pelletan states, does not happen when a considerable quantity of fat is found around the soft swelling, for the purpose of preventing the entrance of intestine or *omentum* into this elevation of the *peritoneum*. These swellings are frequently surrounded with membranes which present perfect coats, and sometimes also contain cysts. The fatty ruptures usually produce neither pain nor other inconvenience, and often remain unobserved throughout the whole life; but if they lengthen deeply into the duplicature of the sickle-shaped ligament of the liver, they may produce great inconvenience, by actually tearing the liver and the *peritoneum* in the movements of the abdominal muscles. Fat-ruptures cannot with certainty be distinguished from omental ruptures, for if, as Scarpa affirms, they be usually tougher and less compressible, this character, however, loses all value in old and adherent omental rupture. Pelletan first pointed out the mechanism of the fat-rupture, when it descends through the inguinal canal. In three cases he found the fatty mass doubly enveloped in *peritoneum*, when the fatty swelling was attached entirely to the *peritoneum*, like the testicle in its descent; and in the protrusion of the fatty swelling into the *scrotum*, the *peritoneum* was drawn over it like a sheath. The fatty swelling in the *scrotum* has the same relations as the testicle

---

(*a*) Memoir.

in its vaginal tunic, being doubly covered by the *peritoneum*, to the one part of which it is firmly and to the other loosely attached. This sometimes also occurs when the fat-rupture passes out by any other of the natural openings in the belly. Although, however, fat ruptures be found in the *scrotum* without any peritoneal covering, the *peritoneum* is more or less withdrawn or not at all connected with them, if they be merely collections of fat in the cellular tissue of the spermatic cord. Although the cavities formed by the double lengthening of the *peritoneum* do not close, but communicate with the cavity of the belly, as does the cavity of the vaginal tunic in congenital rupture, yet the fatty mass usually fills the sac so completely, that very rarely does intestine of *omentum* descend with it and complicate the case. The distinction of this fat-rupture from true rupture is often very difficult. Its gradual growth, and its freedom from pain on pressure, even when very considerable, are characteristic symptoms; but their resemblance to omental ruptures has even deceived the most experienced practitioners. If severe colic or the like accompany such swelling, a mistake is the more easy, and is only first discovered in the operation (SCARPA, CRUVELHIER, OLLIVIER.)

PELLETAN, Clinique chirurgicale, vol. iii. p. 33.

BIGOT, Dissert. sur les tumeurs graisseuses extérieuses au péritoine, qui peuvent simuler des Hernies. Paris, 1821.

COATES, B.; in Cyclopædia of Pract. Medicine and Surgery, edited by ISAAC HAYS. Philadelphia, 1832.

1204. Collections of pus which pass along the spermatic cord, out at the abdominal ring, may diminish or disappear in the supine posture, and increase on coughing and any other exertion; the fluctuation, the presence of symptoms of *psoas* abscess or of *caries* of the vertebral column may, however, guide the practitioner.

1205. Inguinal ruptures must be returned in the same direction by which they have protruded, that is, the external or oblique from below upwards, and from within outwards; and the internal or direct, from below upwards and directly from before backwards.

1206. For the purpose of keeping the rupture up, a truss with a semicircular spring which closely surrounds one half of the *pelvis* is best. In the external or oblique inguinal rupture with a long neck, the pad must press upon the whole length of the inguinal canal; but in internal or direct rupture it must merely press on the external inguinal ring in the direction from before backwards. For the external inguinal rupture with a short neck the truss should be the same.

1207. The strangulation of inguinal rupture may be situated at the external or internal inguinal ring, in the neck of the sac, or in strictures of the body of the sac. If it cannot be removed by the general treatment above mentioned, the operation must be performed with the following special objects:—

1208. The cut through the integuments should always be made, especially in large ruptures, in the mesial line of the swelling, on account of the possible displacement of the spermatic cord, and carefully, because there may be a rupture without a sac (1). In every very large external or oblique rupture the cut should be commenced above the abdominal ring, where the swelling is narrowest, and not further continued till it has been ascertained, by feeling with the finger, whether the spermatic cord do or do not lie upon the hernial sac. When there is much water in the sac, the opening may be made boldly. In addition to the signs already mentioned, (*par.* 1170,) of having laid bare the hernial sac, this circumstance still serves, that as the hernial sac is always connected with the pillars of the abdominal ring, the ring cannot be penetrated before the opening of the sac with the point of the forefinger. If the hernial sac be thin, it can be torn, by seizing it with the forceps; but if it be very thick, frequently a superficial layer only must be divided, by which it is rendered more transparent and rather bluish. In dividing the stricturing part, in well determined external or oblique inguinal rupture, the cut must be made *outwards*, towards the iliac spine, but in the internal or direct inguinal rupture, *upwards and inwards*; in those cases where it is doubtful of which kind the rupture is, *directly upwards*, parallel with the white line, so that the cut may form a right angle with the body of the share-bone. After the complete return of the intestine, the forefinger should be carried through the inguinal canal, into the belly, to ascertain that it is clear and that no portion of intestine remain in it. In imperfectly developed external inguinal rupture, if the strangulation be at the internal ring, the skin, the superficial *fascia* and the tendon of the external oblique muscle must be divided in the direction of the inguinal canal, outwards and upwards, and the seat of stricture cut into *outwards and upwards.*

(1) On account of the circumstances already mentioned, (*par.* 1192,) it is always of importance before operating on an old scrotal rupture on the right side, to consider whether the rupture be formed by the *cæcum* or the beginning of the *colon.* Besides the size and long continuance of the swelling, its knotty condition excites suspicion, which is probable, if the rupture have been slowly produced. So long as it was in the groin it was returnable, but no longer; at least it cannot be perfectly returned so soon as it has descended into the *scrotum*, when the patient, after digestion is ended, and a short time before the bowels are relieved, feels dragging and pressure in the rupture, as well as frequently colicky pains, which subside after going to stool, and if there be in the right iliac region a hollow corresponding to the size of the rupture. In this rupture the stricture only is to be divided, and the adherent intestine covered with compresses, dipped in a mucilaginous fluid, by which in general it gradually returns into the belly.

The various opinions upon the most proper direction for the cut into the stricture, in inguinal rupture, in order to avoid injuring the epigastric artery, have only by the correct anatomical knowledge of its different origin, attained the proper explanation. The direction of the cut obliquely *upwards and outwards*, as proposed by LOUIS, MORAND, SHARP, GUNZ, POTT, BELL, SABATIER, and others, is so far the most proper, as in external or oblique inguinal rupture the artery cannot be injured, and it is by far the most common. (*par.* 1194.) As in the direction of the cut obliquely *upwards and inwards* towards the navel, according to HEISTER, GARENGEOT, LE DRAN, RICHTER, MOHRENHEIM, MURSINNA, and others; or *inwards towards the symphysis*, after LUDWIG and SEILER, only in internal or direct inguinal rupture can the artery be avoided, but in external rupture it can and must be wounded, if it be not granted that thereby really only the internal pillar of the external inguinal ring shall be cut into. The direction of the incision *directly upwards*, proposed by FRANCO, DIONIS, PETIT, CAMPER, ROUGEMONT, and others, was for that occasion the safest, and ASTLEY COOPER (above cited,) still considers it the most proper and safe in all cases. CHOPART and DESAULT gave the most important advice, always to make the cut *towards the side opposite the position of the spermatic cord*, advice, which the knowledge of the corresponding relative position of the spermatic cord and spermatic artery, and a presumption of the various kinds of inguinal ruptures, renders clear (2).

[(2) I do not think CHOPART and DESAULT's counsel is the best that can be taken, if it mean anything more than a caution not to divide the spermatic vessels, which no one would do but by the most gross carelessness. Practically speaking, however, I can say that I do not recollect having had or seen a single instance of operation interfered with by the position of the spermatic vessels, presuming that no pupil of CLINE or COOPER would think of dividing the stricture in strangulated inguinal rupture in any other direction than directly upwards, and neither to the right hand nor to the left. For whatever may be said, it is impossible, I believe, to distinguish, without actual dissection, whether an inguinal rupture be oblique or direct, and therefore any deviation from the directly upward division is hazardous.—J. F. S.]

1209. *Congenital* inguinal rupture, in regard to its treatment, agrees

---

(*a*) Memoir.

entirely with that of external or oblique rupture. The radical cure here takes place earlier, by the constant use of a truss, as the canal of the vaginal tunic has a natural disposition to close; on which account strangulation mostly occurs from a stricture of this canal. The sac is often so contracted, even at its lower end, that the cavity of the vaginal tunic is entirely closed from the rest of the hernial sac. If a portion of intestine protrude with the testicle, it must be attempted carefully to draw down the testicle into the purse, and to keep up the rupture by the truss; if the testicle remain at or in the external inguinal ring and will not descend, a truss, with a concave pad, must be carefully applied. Pressing back the testicle, recommended by many persons, is very painful and dangerous, as degeneration of the testicle may be caused by the pressure of the truss. If the rupture adhere to the testicle, and keeping up the former be very painful, an operation and division of the adhesion is indicated. If strangulation be present and the operation necessary, (which even in the first days after birth may happen,) it must be performed with particular caution, that the testicle be taken care of. Any adhesion between the testicle and the protruded parts must be divided. If water as well as intestine be contained in the congenital rupture, it can be determined, after having returned it with the intestine, and putting the finger on the ring by raising the patient, when the water first, and then by coughing or the like, the intestine protrudes. If in these cases a truss be applied, in most, the water is gradually absorbed.

1210. After completing the operation for inguinal rupture, and cleansing the wound, the edges of the skin should be brought together, with some interrupted stitches, and between them strips of plaster applied, and covered with wadding; to the region of the inguinal canal a many-folded triangular compress is to be applied and kept in place with a T bandage. The patient should lie in bed on his back, with his thighs drawn up towards the belly, and supported by a bolster beneath the knees. The after-treatment is to be conducted by the rules already laid down.

1211. In the operation for inguinal rupture, *without opening the hernial sac*, after making the proper cut of the skin a small aperture is to be made in the tendon of the external oblique muscle, a little above the external inguinal ring, and a director introduced, with which it is sought to find the seat of stricture, and then it should be directed towards the outer or inner inguinal ring and the stricture divided with a knife introduced upon the director (Key); or the hernial sac is to be drawn a little down, whilst the muscles are raised by an assistant, and then the stricture being rendered visible in the opening of the tendon, should be divided (A. Cooper.)

1212. External inguinal rupture may originate, in women, in the lengthening of the *peritoneum*, which sometimes accompanies the round ligament of the womb, and is comparable to *congenital* rupture in the male sex.

[This lengthening of the *peritoneum* was first described by Nuck (*a*) who called it a *diverticulum*, and said it was about half an inch long and not constant. Cloquet (*b*) speaks of it by the name of Nuck's canal, as "a cylindrical tube terminating in a point or in a rounded *cul-de-sac*, of which the length and size varies; sometimes, on the contrary, it is a little flask with a narrow neck which communicates with the belly," and that he has "found them not only in female *fœtus*, but also in young girls and women of all ages." (p. 41.)

As to the frequency of congenital rupture in the female, Allan Burns says (*c*) that he has seen seven cases, in six of which he "found the anterior side of the inguinal

as GIMBERNAT's ligament, which diminishes by its own breadth the opening from the belly to the thigh, between POUPART's ligament in front and the *pelvis* from the pubic spine to the lower front iliac spine, which is also still further lessened upon the outer side by the conjoined mass of the *m. iliacus internus* and *psoas magnus*, as they pass from the *pelvis* into the thigh, to their insertion in the little *trochanter*. The space then actually left is scarcely more than an inch wide to the inner side of the junction of the hip and share bones, and consequently before and above the inner half of the *acetabulum*, or hip-socket and a little to its inner side, and through it the femoral vessels pass. But this aperture, the *crural ring*, has further boundaries. As from POUPART's ligament, or the *crural arch*, as it is often called, is expanded above, the tendinous covering of the belly, below the upper front iliac spines, and of the *m. recti* upwards to the pit of the stomach having in it the external abdominal ring, so from the lower edge of the ligament descends an extensive tendinous expansion which encloses all the muscles of the thigh and is lost about the knee-joint, and commonly called the *fascia lata*. This sheath seems to begin by a sharp angle from the lower edge of POUPART's ligament, where GIMBERNAT's ligament ends above; as it continues outwards it deepens, assuming a crescent or sickle-like shape, forming the falciform process, till it stretches down the whole length of the thigh. But before doing this, and at the distance of about an inch and a half from POUPART's ligament, corresponding also to the same distance from the oblique crease in the skin, which separates the belly from the thigh, it curves suddenly inwards and upwards, spreading as it rises in front of the *m. pectineus*, above the origin of which it is fixed into the *pelvis* as far as the pubic spine. A large opening of an irregular oval form is thus left in the otherwise complete tendinous sheath of the muscles of the thigh, and to it is given by LAWRENCE the name of *lower or anterior opening of the crural canal;* over the inner lower edge of which the great saphenous vein is seen mounting to enter the inside of the femoral vein, which with the great artery it accompanies, are here uncovered by tendinous sheath, but still covered in a peculiar manner.

It will be recollected that when speaking of the transversal *fascia* in the description of the parts of inguinal rupture, that its lower part at the bottom of the belly was mentioned as consisting of two portions, the front and outer or iliac portion continued along the margin of POUPART's ligament to the upper iliac spine, forming the outer half of the internal abdominal ring, then bending round behind the *peritoneum* and spreading over the front of the *m. iliacus internus* and *psoas magnus*, as they fill the ventral cavity of the hip-bone, and there assuming specially the name *fascia iliaca*. The hinder inner, or pubic portion of the transversal *fascia* was also mentioned as forming the back of the inguinal canal, and the inner half of the internal abdominal ring and then stretching away outwards in a sharp edge up to the spine of the hip-bone, behind the front portion, there terminated, and might with equal propriety be called *fascia pudica*, it being remembered, however, that neither it nor the so-called *fascia iliaca* are other than continuations or processes of the transversal *fascia*. In the angular track between POUPART's ligament in front, and the *m. iliacus* and *psoas magnus* behind and on the outer side, and the edge of GIMBERNAT's ligament and the angle of the share-bone, behind and on the inner side, these the iliac and pudic portions of the transversal *fascia* unite in a kind of seam on each side, but separated in the middle at the gap formed by the crural arch for the passage of the femoral vessels. Thus far completes the description of the transversal *fascia* in the belly; part of which only, namely, that immediately connected with inguinal ruptures, had been described. It remains now to speak of this *fascia* as connected with femoral rupture.

The aperture behind POUPART's ligament, or the crural arch, and called by HEY the *femoral ring*, gives passage to the femoral vessels, which, whilst in the *pelvis*, lie upon the iliac portion of the transversal *fascia*, between it and the *peritoneum*, but reaching the crural ring, escape from behind the *peritoneum*, and then are placed between the just-mentioned iliac portion of the transversal *fascia* behind, and its pudic portion in front. Here the iliac and pudic *fasciæ*, having joined so as to form a corresponding opening to the femoral ring, are continued down into the thigh, in the shape of a wide, but much flattened funnel, behind the *fascia lata*, but uncovered by it, as the funnel descends behind its oval opening, and containing within it the femoral vessels, is called the *femoral sheath*, the hinder or iliac portion of which descends only to the origin of the deep branch of the femoral artery; whilst its front, or pubic portion, extends along the trunks of the femoral vessels till they penetrate the tendon of the *m. triceps adductor femoris*. A process passes from the front to the back of the sheath, along its whole length, dividing it into two distinct canals, in the outer of which is contained the femoral artery, and in the inner the femoral vein. Immediately above the lower edge of the oval opening of the *fascia lata* is an opening on the inside of the femoral sheath, through which the great saphenous vein penetrates to empty itself into the femoral vein. Above the former, the absorbent vessels penetrate, as Astley Cooper (a) describes, "through the inner side of the sheath, near the *pubes*. In the male subject I have seen them enter the sheath in a cluster, through a single hole in this *fascia*; but in both sexes the *fascia* is generally rendered cribriform, by these vessels passing through a variety of small openings." (p. 9.) He also further states, what I must confess I have never observed, that "if the sheath be opened, the contents will be found separated by *two* membranous *septa*, one passing between the artery and vein, and the second, equally distinct between the vein and the absorbents. * * * The contents of the sheath differ in their attachments to the bag; the artery and vein are seen completely filling up the space in the sheath which is allotted to them; while the absorbents are loosely connected by means of cellular membrane and fat, which, not affording sufficient resistance to the pressure of the abdominal *viscera*, occasionally allows the descent of a *hernia*." (p. 10.) This portion of the sheath is commonly, in health, called the cribriform *fascia*, and it is between it and the femoral vein that femoral rupture first enters the sheath, and then, protruding its inner side, has been called by Astley Cooper the *fascia propria* of the rupture, a most inappropriate name, as it might lead to the supposition of a new formation instead of the simple protrusion of an old structure in these cases. In regard to this covering of the femoral sac, Cooper says:—"A thin *fascia* naturally covers the opening through which the *hernia* passes and descends on the posterior part of the *pubes*. When the *hernia*, therefore, enters the sheath, it pushes this *fascia* before it, so that the sac may be perfectly drawn from its inner side, and the *fascia* which covers it left distinct. The *fascia* which forms the crural sheath, and in which are placed the hole or holes for the absorbent vessels, is also protruded forwards, and is united with the other, so that the two become thus consolidated into one." (part ii .p. 2.) Cloquet also describes the closure of the top crural sheath in a very similar manner. "The upper orifice of the crural canal (sheath) is closed," says he, "by a membranous partition, which opposes the formation of crural rupture, as well as the entrance of the finger when pushed from above downwards, above the crural arch. This partition forms above the arch a sort of diaphragm-cellulo-fibrous, whitish, thick, and very resistant in some subjects; simply cellular, weak, and readily yielding in others. I propose giving it the name *crural septum*. It arises completely around the upper opening of the crural canal, is thickish, and its fibres are most commonly transverse in front, towards the crural arch. Within it proceeds from the cellular tissue behind Gimbernat's ligament; or, rather, from the concave edge of that ligament itself, conjointly with the inner wall of the crural canal (sheath) itself. Externally it is blended with the femoral sheath, and the laminar tissue encircling the epigastric artery, on the outside of which cellular tissue fills the space between the crural arch and vessels. Its upper abdominal surface is concave; its lower, towards the crural canal concave; but sometimes both surfaces are flat. It always presents one or more apertures for the passage of the lymphatic vessels, and sometimes the upper part of the crural canal seems merely closed by a fibro-cellular network. One of these openings, larger than the others, is central, and penetrated by an oblong lymphatic gland, and will admit the finger." (pp. 73, 4.) Lawrence says that he has not found, on dissection, either Cooper's "thin *fascia*," or Cloquet's "membranous partition," and is "disposed to refer the origin of this *fascia propria* to the condensed fibrous substance. which completes the crural sheath on its inner or mesial side." (p. 478.) And with his views in this respect I fully concur. —J. F. S.]

1215. Although the femoral ring is a larger opening than the abdominal, yet femoral is more rare than inguinal rupture, because the intestines do not press so directly upon this part; it is not originally open, nor does any organ descend through it. Femoral rupture is more frequent in women than in men.

1216. Femoral rupture commences with a little roundish deep-seated swelling beneath Poupart's ligament, which as it enlarges spreads aside, so that its base increases in breadth, and its greatest diameter corresponds to the oblique direction of the groin (1). The swelling never attains the size of inguinal rupture; it may, however, spread over the femoral vessels and nerves, and produce a sensation of numbness, or œdematous swelling of the foot of the affected side. In men, the distinction between femoral and inguinal rupture is easy, because the latter closely follows the direction of the spermatic cord; but in women it is more difficult, because the cord does not exist, and the abdominal is nearer the femoral ring (2). Femoral rupture is easily distinguished from a bubo, and from a collection of pus; the *diagnosis* is, however, more difficult when the rupture is accompanied with a swelling of the glands (3).

(a) Hernia, part i.

[(1) Femoral rupture commonly after descending a little down and protruding the sheath inwards, turns upwards upon Poupart's ligament, so that the bottom of the sac is above the mouth. Astley Cooper, however, states that "it sometimes happens that instead of crossing the thigh in the direction of the crural arch, it extends downwards along the edge of the crural vein and the *vena saphæna major*. (p. 1.) The tumour does not quit the sheath for the crural vessels. The appearance of this disease is that of a general swelling of the *fascia* on the inner side of the femoral vein, but without its producing any circumscribed tumour. The part swells whenever the patient coughs or uses any considerable exertion, but the swelling diminishes though it does not entirely subside, when he stands at rest. * * * I believe it to be not an unfrequent variety, as I have met with it three times in the dead body, and it existed on both sides in each. * * * It is continued downwards within the sheath, passing anteriorly to the femoral vein, and descends as far below the crural arch as the sheath will allow, the distance being in general from two to three inches." (p. 25.) Callaway tells me one such case occurred under his care, and was at first supposed to be *varix* of the femoral vein, its true nature was, however, discovered, and a truss was applied with advantage.

(2) In ordinary cases I have never seen any difficulty of distinguishing femoral from inguinal rupture in women; and cannot conceive it possible, except whilst the latter is in the inguinal canal, or on the point of passing through the external abdominal ring; but even then it is not difficult to determine, as the swelling of femoral rupture can be pushed down into the thigh, and Poupart's ligament either thereby exposed or the fingers passed between the rupture and it, which cannot be done by pressing down inguinal rupture, as thereby Poupart's ligament is more hidden.

(3) Besides those here mentioned, there are other swellings in the upper part of the thigh or groin liable to be mistaken for femoral rupture. Astley Cooper mentions an enlargement of the crural vein, which dilated when the patient coughed, (in consequence of the return of blood into the belly, made by the pressure of the bowels upon the iliac veins,) disappeared in the recumbent, and reappeared in the erect posture. * * * It was easy to detect the nature of the case, for although it disappeared in the recumbent posture, it was immediately reproduced, although he continued in that posture, by pressing on the vein above the crural arch, and retarding the return of blood." (p. 4.) Tumours also, either fatty or encysted, may occupy the seat of the rupture, and be mistaken for it. Of the latter there is an example in St. Thomas's Museum.—J. F. S.]

1217. The coverings of femoral rupture are, *first* the external skin; *second*, cellular tissue and glands; the layer of the former is often very thick and loaded with fat; *third*, the superficial layer of the *fascia lata* (1); and *fourth*, the hernial sac, the protruded part of the *peritoneum*, which is covered on its surface with a layer of loose cellular tissue.

These coverings are not the same in all cases; a rupture of increasing size may protrude through the aperture by which the *vena saphena* has entered, so that it is then for the most part covered only with skin and subjacent cellular tissue. Most commonly a portion of the *ileum* is included in femoral rupture, more rarely the *omentum*, and extremely seldom a portion of the bladder.

[(1) This is erroneous; the *fascia lata* never covers femoral rupture, which passes, as already mentioned, through the oval opening, and the third covering is the protruded *sheath of the femoral vessels*, as I have already described.

I recollect seeing Green operate on a case in which, when the so-called *fascia propria* was exposed, it had a nodulated form, and gave some idea of intestine covered only with its peritoneal sac; but on carefully cutting through, a mass of soft fat was found beneath it, under which was the sac.

In another case under my own care, having cut through the *fascia propria*, as seemed, I thought I had reached the peritoneal sac, and dividing it, as mall quantity of fluid was discharged, which led me to suppose I had opened the sac, but what I supposed to be intestine remained very immovable, and led me to doubt. Upon examining what was thought to be mesentery I found the vessels running in all directions, and the part itself semitransparent; I therefore carefully cut through it, and immediately about a tablespoonful of fluid escaped, and a knuckle of intestine was exposed.—J. F. S.

A very remarkable case of femoral rupture is mentioned by **Berard** (*a*), which contained the Fallopian tube, and a large quantity of fluid. It had commenced two years previously in a small tumour, which was reducible, but she neglected wearing any bandage. In December, 1837, the growth had become more rapid, and the swelling, which was in the right groin, larger than a hen's egg, stretched somewhat towards the *abdomen* and right *labium*, with a broad base, and smooth surface, except on the upper inner side, where a nipple-like process, as big as the top of the finger protruded, and the skin covering it was thin and bluish. The tumour fluctuated, and was transparent, and she says returns into the belly when she lies down. It was presumed to be a serous cyst developed in the part, or an old hernial sac closed by adhesion at the neck, and become dropsical. She had also a hard round body, as big as a turkey's egg, protruding above the *pubes*, which, on examination, by the *vagina* was found to originate from the womb. The first-mentioned swelling was punctured with a trocar, and six or eight ounces of citron-coloured frothy *serum* discharged, which coagulated with heat. A round body, as large as a small nut, and irreducible, was felt in the femoral ring, and ceased to be felt behind the crural arch. On the fifth day after the operation the sac suppurated, and she died on the seventh. On *examination* the interior of this cavity was found lined with albuminous exudation, and it communicated by a free opening with the peritoneal cavity behind **Poupart**'s ligament. It contained nothing but the Fallopian tube in a state of considerable hypertrophy, without adhesion to the interior of the sac, but closely united to the anterior part of the circumference of the sac. The tissue of the womb was healthy, except being distended by an enormous fibrous tumour.]

1218. The epigastric artery is on the outer side in internal femoral rupture, and ascends on the outer side of the hernial sac, where it crosses the spermatic cord, which runs on the upper and inner side of the rupture. The variations in the course of the epigastric and obturator arteries are here of the greatest importance. If the obturator artery arise from the external iliac or from the epigastric, or both from the crural artery, when it has passed below **Poupart**'s ligament, the obturator artery runs along the inside of the hernial sac, down into the *pelvis*. In the same direction, frequently passes a not inconsiderable branch of communication from the epigastric to the obturator artery. The observations on the frequency of these different origins do not always precisely agree; the origin of the obturator artery is, however, almost more common from the epigastric, than from the internal iliac artery (*b*).

1219. The spermatic cord surrounds the upper part of the neck of the hernial sac, describing a semicircle inwards, so that the neck of a femoral rupture lies between the epigastric artery and the spermatic cord, at an equal distance from both.

1220. Femoral rupture is often very difficult of reduction owing to its depth. The *taxis* must, in a small femoral rupture, be applied directly from before backwards; but in a large one, first from above downwards, and then from before backwards, the thigh being also much bent at the groin. The fingers of both hands are to be applied on the swelling, and attempts made gently, but continuously, to return the parts. In order to keep the femoral rupture up, a similar bandage to that used in inguinal rupture is employed, only with a shorter neck, because the femoral ring is

---

(*a*) L'Expérience, April, 1839. — British and Foreign Medical Review, vol. x. p. 267.

(*b*) **Cloquet**, above cited.—**Hesselbach, A. K.**, Ueber den Ursprung und Verlauf der unteren Bruchdecken Schlagader und der Hüftbeinloch Schlagader. Nachtrag zu seiner Schrift: Ueber die sicherste Art des Bruchschnittes in der Leiste. Bamberg und Würzburg, 1819. 4to.; with six Engravings.—**Tiedemann**, Erklärung seiner Abbildungen der Pulsadern, p. 288-298.

nearer the iliac spine, than to the front inguinal or external abdominal ring. The direction of the neck of the bandage must correspond to that of POUPART's ligament, to wit, from the side towards the share-bone. The edge of the pad must not descend over the bend of the groin.

1221. Femoral rupture may be strangulated in the external or in the internal aperture for the vessels; the strangulation is generally very severe, and if reduction cannot be effected, the operation is soon indicated.

The strangulation may also be situated in the neck of the sac, especially if a truss have been worn for a long time. JAËGER's assertion (*a*) that no case of strangulation by the neck of the sac is known, I must deny. I would add, that in two cases the reduction of the intestine was impossible, although the femoral ring was so considerably cut into that the finger could be readily passed into it, and turned about in every direction. In both cases the strangulation was in the neck of the sac, after the division of which the bowel was easily reduced.

[KEY considers the usual seat of stricture in femoral rupture to be "a tendinous band, which joins the *fascia transversalis* to the posterior margin of POUPART's ligament, and which is quite distinct from GIMBERNAT's ligament, upon which so much stress is laid by some as constituting the stricture." (p. 14, *note*, part ii.)]

1222. The cut through the skin in the operation for femoral rupture should have an oblique direction, corresponding to POUPART's ligament, and should extend half an inch over the swelling towards the iliac spine and the pubic *symphysis*. The cellular tissue is then to be divided as described (*par.* 1170) in the direction of the cut in the skin. The subjacent fat, which in stout persons is often very considerable, has a peculiar consistence, and often a resemblance to a piece of *omentum*, must be carefully separated from the bands, and the upper layer of the *fascia lata* cut through (1); the hernial sac is then to be exposed and opened. A case may occur in which the rupture protrudes through the opening of the upper layer of the *fascia lata*, in which instance, by cutting through the skin and cellular tissue, the operator comes at once upon the hernial sac. The opening of the hernial sac requires the greatest care, as there is always but little fluid, and frequently only a small loop of intestine uncovered by *omentum*.

The oblique cut, corresponding to the great diameter of the swelling, (SCARPA, ZANG, and others,) is in general most suitable, because by dividing the upper layer of the *fascia lata*, POUPART's ligament, is at the same time relaxed. In large swellings, or in stout persons, a T-shaped (COOPER, LAWRENCE, and others) or a transverse incision (PELLETAN, DUPUYTREN) may be made. The directly vertical incision is objectionable.

[(1) It must not be forgotten that what CHELIUS here and elsewhere calls the upper layer of the *fascia lata* is really the femoral sheath.—J. F. S.]

1223. If the strangulation be caused by the outer aperture of the femoral vessels, or by the opening of the external layer of the *fascia lata*, the tendinous edge of this aperture must be carefully cut into. If the strangulation be in the femoral ring, different modes of treatment are proposed.

(*a*.) In women the point of the forefinger or the director should be introduced between the neck of the hernial sac and the intestine, the button-ended bistoury passed upon it, and the inguinal ligament cut into inwards and upwards.

(*b*.) In men the button-ended bistoury should be introduced upon the director which has been passed on the inside, to protect the spermatic cord, and the inguinal ligament should be divided horizontally inwards, or rather a little obliquely upwards, two or three lines deep (SCARPA.)

(*a*) Handwörterbuch der Chirurgie, vol. iii. p. 591.

DUPUYTREN cuts obliquely from below upwards along the edge of the outer inguinal ligament, in the direction by which the spermatic cord descends.

(*c.*) For the purpose of more surely preventing the injury of the epigastric or obturator artery, ARNAUD's hook should be introduced under the inguinal ligament, so as to draw it obliquely up towards the navel, whilst the power of the pull should be kept up by the finger introduced beneath POUPART's ligament, and the intestine pressed back. If the inguinal ligament be not thereby sufficiently stretched, some slight cuts, only a line deep, must be made in its edge, and then it must be raised up with ARNAUD's hook (SCHREGER.) In the same way LE BLANC's dilator is to be used. Also by introducing the forefinger between the inner surface of the hernial sac and the edge of GIMBERNAT's ligament, the latter may be stretched, or even torn (RUST and others) (*a*).

For an account of the numerous modes of proceeding in the operation for femoral rupture, see

SCHREGER, Grundriss der chirurgischen Operationen, vol. i. p. 254. Third Edit.

1224. The danger, which, in the above-described course of the obturator and epigastric arteries, is run from the practice *a* and *b*, on account of the injury of these vessels, the favouring of the recurrence of a rupture by the bloodless expansion, according to *c*, further, the circumstance that the parts suffer considerable bruising, and the mere extension in many cases is not sufficient for the removal of the strangulation, have decided HESSELBACH to the practice (which in a manner resembles the earlier practice of BELL, ELSE, and others) of seizing the exposed lower edge of the inguinal ligament with the forceps, and cutting into it layerwise, from below upwards, two lines deep, and to introduce the forefinger between the intestine and the seat of strangulation. If the cut be insufficient, it must be lengthened through the fibres of the *aponeurosis* of the external oblique abdominal muscle above the spermatic cord, which is raised by an assistant, and the inner inguinal ligament should be cut into in the same way (*b*).

1225. This practice, although safer, on account of the deep situation of the femoral ring, especially in stout persons, is accompanied with great difficulty. That proposed by SCARPA and DUPUYTREN seems preferable to all other, if attention be paid to the following circumstances; the point of the forefinger is to be so introduced between the protruded part and GIMBERNAT's ligament, so as to bring the nail behind its sharp edge; COOPER's hernia-knife with the probe point, is to be passed upon the finger, behind the sickle-shaped edge of GIMBERNAT's ligament, so that the edge does not extend above it. The edge is then to be pressed by the front of the finger against the ligament, so as to effect its division by pressure, and not by drawing. A smaller cut of one or two lines' extent is often sufficient for the reduction of the protruded parts, by slightly pressing in with the finger. If this be insufficient, the incision must be repeated (*c*).

[The division of GIMBERNAT's ligament is useless; the stricture in femoral rupture is almost invariably in the neck of the sac itself, which must be divided, or the rupture will not return.

(*b*) HESSELBACH, A. K., die sicherste Art der Bruchschnittes in der Leiste. Bamberg und Würzburg, 1819.

(*c*) SCARPA, above cited.—LANGENBECK, above cited, p. 80.—RICHERAND, Histoire des Progrès recens de la Chirurgie, p. 62.

In operating on femoral rupture, without opening the sac, **Key** observes:—"It may be as well to disturb the subjacent cellular membrane as little as possible, as inflammation is less likely to follow, and to assume the form of erysipelas. For this reason the inverted T incision, usual in the operation for femoral *hernia*, may be in most cases reduced to a single incision, either at right angles to **Poupart's** ligament, or in a transverse direction across the tumour. In patients who are spare, and in whom the neck of the sac lies at no great depth from the surface, it is unnecessary to disturb the cellular membrane by turning aside the flaps of the integuments. This will diminish the suppurative inflammation, and in such cases will afford ample room for the operation. I have not made trial of the perpendicular form of incision, but a single transverse one I have found sufficient when the integuments have been loose and the tumour not large. The superficial *fascia* adheres firmly to the common integuments, and is usually turned aside with them, especially when the latter are pinched up for the purpose of making the first incision. The *fascia propria* is therefore quickly exposed, and forms the first distinct covering of the tumour, being darker than the more superficial cellular investment. It is under the outer layer of this *fascia* that the adipose structure is formed, and which often assumes the appearance of *omentum*. The director easily makes its way under this fatty matter as far as the neck of the sac, which lies deeper than the operator at first supposes. The point of the director should be applied rather to the inner than to the outer part of the neck of the sac, as it will be found more easily to pass under the stricture at this part. It should not at first be attempted to be thrust under the stricture, as the firmness of the parts forming the stricture would resist it. But the seat of the stricture being felt, the operator should depress the ends of the director upon the sac, which will yield before it, and then, by an onward movement, the director slides under the stricture." (pp. 143, 44.)]

1226. The return of the intestine, the dressing and the treatment after operation are to be conducted in the same way as already described in inguinal rupture.

1227. The *external femoral rupture*, which consists in the protrusion of the *peritoneum* and of the *fascia iliaca* on the outside of the femoral vessels, between them and the front upper angle of the hip-bone, and is gradually developed, forms at the place mentioned a moderately raised swelling, which, becoming narrower below, ascends, however, obliquely inwards, and terminates with a blunt point in the region of the lesser *trochanter*. The finger cannot in the least be brought under either of its edges. If in its further growth the rupture overcome the anterior iliac *fascia*, the form and direction of the swelling is changed; a new one is developed beneath the old swelling, which always extends further between the *fascia lata* and the muscles of the thigh. The mouth of the rupture is formed by the outer part of **Poupart's** ligament and the iliac spine; on its inner side lies the femoral artery, and upon it the circumflex iliac artery. The neck of the sac is the widest part of it lying within the belly; its inner wall lies under the semi-lunar bridge of the posterior iliac *fascia*, its outer on the *m. iliacus internus* and *psoas magnus*. The body of the sac lies behind the anterior iliac *fascia*, near it outwardly lie the *m. rectus* and *vastus externus femoris*, near it inwardly the femoral vessels and nerves, partially covered by it, and upon or before it the *m. sartorius* and part of the *fascia lata*. The bottom of the sac, its narrowest part, lies on the *trochanter minor*. The coverings of this rupture beneath the skin are, *first*, the femoral ligament upon the inner greater half, and the *m. sartorius* upon the outer lesser half of the hernial sac; *second*, a layer of tough cellular tissue, in which small blood-vessels and nerves run; *third*, the anterior iliac *fascia*; *fourth*, the posterior iliac *fascia*, which is very delicate, and allows, *fifth*, the hernial sac, which it completely envelopes, to show through. **Hesselbach** considers a weak constitution, and the existence of the *m. psoas minor*, by which a cup-like hollow is formed, as disposing to this rupture. As long as this rupture is enclosed in the anterior iliac *fascia*, it cannot well be strangulated, because the neck is the widest part of the sac; but if that *fascia* be torn by great violence, then, according to HESSELBACH, strangulation may follow. The *taxis* is to be applied from below upwards; and if the operation be necessary, it is only possible, according to HESSELBACH, to avoid wounding the circumflex iliac artery, which always lies in front of the neck of the sac, by the division layer-wise of the strangulating parts (*a*).

[ASTLEY COOPER observes, that "it is by no means common to meet with deviations from the usual structure of crural hernia," and describes three varieties; *first*, that in which "the fascia usually covering the hernial sac has given way so as to allow a portion of the tumour to pass before it; thus dividing the tumour into two parts, with a sort of hour-glass contraction between them," (p. 25, part ii.) very similar to which appears HESSELBACH's case, quoted by KEY, where "the sheath had given way in different parts so as to givethe sac an appearance of five small tumours, which was probably owing to the apertures through which the absorbents pass having yielded, while the general texture of the sheath had resisted pressure." (p 25, *note*, part ii.) *Second*, "when the tumour does not quit the sheath for the crural vessels." *Third*, "that in which the *hernia* is formed in part within the sheath, and also in the common way." (p. 25, part ii.)

I have had three cases of femoral rupture which seem distinct from either of those mentioned, and were furnished with a second sac, produced, I presume, by rupture of the original one.

Case 1.—S. B., aged fifty-six years, a stout, healthy, but flabby woman, was admitted into St. Thomas's Hospital on the afternoon of

Sept. 23rd, 1837, having been subject of rupture on the right side for the last nine years, during the latter four of which she has worn, though irregularly, a cup-truss, as the protrusion could not be entirely returned. Within the latter period the rupture has descended so largely five times as to cause severe vomiting, but has been relieved. On the *20th ult.* her bowels were moved, and not since. Next afternoon she was attacked with severe vomiting, and yesterday the *taxis* was employed severely, but without relief, and the symptoms continued up to the period of her admission, when she was immediately put in the warm bath, which produced complete prostration, and attempts at reduction were made, but without success.

In the *evening* I saw her, and she had then recovered the effects of the bath, but she was vomiting stercoraceous matter, had continual eructations, and hiccough, which had been through the whole day, otherwise she was tranquil, and her countenance cheerful. The belly was tender, but not much distended.

A large oblong tumour extended from the pubic spine to within an inch of the upper front iliac spine, about three fingers in breadth, covering POUPART's ligament, and having the appearance of an enlarged mass of inguinal glands, very firm and unyielding, and the skin covering it very livid, from the previous severe handling. A second swelling occupied the place of femoral rupture, not exceeding the size of a walnut, separated from the former by the crease of the groin, and rather nearer the *pubes* than usual. This seemed without doubt a femoral rupture, and gave a sense of indistinct fluctuation when the swelling on the groin was pressed. I was in much doubt of the character of the larger swelling, whether it were a mass of enlarged glands further swollen and inflamed by the handling, or whether an encysted tumour, or whether a rupture; but neither its history nor situation led to the latter supposition.

As the swelling had been so severely mauled, I thought it best not to make any violent or long-continued efforts to return the rupture, and, not succeeding, proposed to her an operation, to which, however, she would not consent. The symptoms continuing throughout the night, and her countenance becoming anxious, she was at last persuaded to submit; and after consultation with my colleague GREEN, on the following day, *Sept. 24th, noon*, I proceeded to operate on the smaller tumour, in the same way as for femoral rupture. Nothing unusual occurred except that, on opening the sac, no fluid escaped; a portion of *omentum*, about as large as a walnut, turned out, but no intestine could be found. I then passed my finger up towards the mouth of the sac, into the aperture of which I could just introduce it. No alteration having taken place in the

---

(*a*) HESSELBACH above cited, and his Lehre den Eingeweidebrüchen, vol. i. p. 172.—ZEIS, Dissert. Herniæ cruralis externæ historia. Lipsiæ, 1832.

tumour on the groin, and the *omentum*, in the sac just opened, seeming scarcely sufficient to account for the severity of the symptoms of strangulation, we determined on narrowly examining the sac, to ascertain whether it communicated with the large swelling. In carrying my finger round the hernial cavity for this purpose, it suddenly passed into an aperture on the outer side, and, being pushed onwards, entered the large swelling, and passing along it nearly as far as the iliac spine, could be readily felt, and not deeply, beneath the skin, which was then slit up on my finger, and thereby a large mass of healthy *omentum* exposed, which, being raised, about four inches of small intestines, chocolate-coloured and bright, but with a few patches of adhesive matter beneath its peritoneal coat, which also adhered slightly to the *omentum*, came into view. The mouth of the sac was speedily found, and my finger with little difficulty passed into the belly; but the gut would not return till the aperture had been enlarged with the knife. About four ounces of *omentum* were cut off, and the wound dressed; she recovered without an untoward symptom. I presume in this case that the hernial sac had burst, but how or when, the history of the case gave no information, and that the protruded bowel and large portion of *omentum* had no proper sac, but had merely formed themselves a cavity in the cellular tissue.

Case 2.—A. B., aged fifty-five years, a healthy, stoutish woman, of loose texture, was admitted

Feb. 24*th*, 1842, having been the subject of femoral rupture on the right side for twenty years, the latter half only of which she has worn a truss. On the morning of the 21*st ult.* her bowels were last moved, and, having exerted herself more than usual during the day, the rupture increased beyond its ordinary size, and could not be returned as previously. She was constantly vomiting during the night; and next day was bled, put in the warm bath, and had the *taxis* applied for two and a half hours without relief. The vomiting ceased in the course of the day, and nothing was done for her yesterday except giving some sulphate of magnesia in the evening, which, not operating, castor-oil was given this morning, but without relief. She has now (noon) a little hiccough, and frequent fetid eructations, but has not vomited since the 22*nd ult.* The belly is generally tender, and the pulse small; but the countenance is little distressed.

In front of Poupart's ligament there was a large swelling, extending to within two inches of the iliac spine, but not much elevated, and from its inner extremity a second swelling descended in the usual situation of femoral rupture, but pyriform rather than globular, and passing down lower in the thigh than usual. A distinct indentation existed between the two swellings, as if they were separated beneath the skin; and at this part was a scar, the result of an abscess five years ago. The fingers could be passed behind both swellings, especially the inner, which was tender; but neither were inflamed, nor appeared to have been much handled. The general resemblance to the former case was very strong. The *taxis* was employed both before and after the warm-bath, but without avail, and with her consent the operation was performed, at 2, P.M., upon the inner swelling. After cutting through, and turning off the skin and superficial *fascia*, an absorbent gland was found on Poupart's ligament, sending inwards a neck to join another below it; and three absorbent vessels were seen entering the former gland, having risen up from the femoral sheath, and by their tightness produced the depression between the two swellings already mentioned. The neck of gland was divided, and the *fascia propria*, which was very tough and almost fibrous, slit up on a director, exposing the hernial sac, which was so much larger than seemed at first, that I was obliged to widen the opening in the skin by cutting it inwards. The sac was then opened, and a small quantity of fluid escaped, followed by protrusion of *omentum;* and the cut, having been completed with a bistoury upon the finger, a knuckle of intestine, about three inches long, was found on the inner side of the swelling. I then passed my finger down to the stricture, and could enter just the tip within it; but the size of the other swelling rendered it so deep that I found it necessary to enlarge the external cut upwards previous to division of the stricture, which was made sufficient to admit the finger readily into the belly. The gut being congested, but bright, and, having examined the strictured part, and emptied it, I returned the bowel without difficulty into the belly. On carefully examining the hernial sac, in reference to the remaining swelling, I found an aperture in its outer wall close to Poupart's ligament, through which my finger readily passed into the tumour, the extent of which outwards was ascertained by the finger being buried up to the knuckle. The cavity contained nothing but soft *omentum*, which, having in vain attempted to withdraw, I thought best left alone. That *omentum*, however, in the opened sac, though healthy, being large in quantity, I cut off, having previously introduced a double ligature, and tied it on each side, which prevented any bleeding. She was then put to bed, and recovered without any hindrance.

Case 3.—A. W., aged fifty-five years, a spare, healthy woman, was admitted in the afternoon of

Nov. 4*th*, 1828, having ruptured herself on the right side ten years ago, since which time she has worn a truss constantly, which, however, has not fitted, and the rupture has been so much incarcerated five or six times as to need assistance for its reduction; but it does not appear certain, from her account, that its entire contents have been always returned. Yesterday evening, (her bowels having been twice relieved during the day,) whilst engaged in her usual occupation, mangling, the rupture came down beneath the truss, which she took off, and, having returned the protruded parts, felt no farther inconvenience till 11 o'clock this morning, when it again came down, and, having attained larger size than usual, became painful, and made her sick and faint. She could not return the rupture, nor could her medical attendant, who twice employed the *taxis* during the afternoon, and then sent her on that evening to the hospital, where the warm-bath and *taxis* were resorted to, but without avail. When I saw her, at 6, P.M., she had been constantly retching for the last five hours, and so continued, raising, however, nothing more than a little transparent, colourless fluid. She had frequent eructasions, increased by any pressure on the swelling; the belly is full, but not tender, and the complains only of pain at the lower part, near the rupture; pulse small; countenance pallid and anxious; the bowels have not been relieved since yesterday.

Upon POUPART'S ligament was a large tumour of an oblong shape, extending from about three fingers' breadth to the inner side of the upper iliac spine, into the right *labium pudendi*. It was more prominent, bulky, and rounded, at its outer end, gradually narrowed as it proceeded inwards, and reaching the lower part of the *mons Veneris*, bent down at an angle, and descended for the distance of an inch into the *labium*. The upper outer part of the swelling was firm and unyielding, but the labial portion soft and fluctuating on pressure. The appearance of the tumour, which was such as might be supposed to depend on inguinal and femoral rupture existing simultaneously, rendered the *diagnosis* puzzling. But finding it possible to get my fingers under both ends of the swelling, although I could not pass them behind its centre, I concluded that the case was one of femoral rupture, accompanied with variety. This view was supported by the patient's statement, that till this morning, although often very large, the swelling had always been in the thigh alone, and not in the *labium*, where it first appeared only to-day. As the case was one of which I knew none like, I gladly availed myself of my friend the elder TRAVERS's kind opinion, which, concurring with my own, it was determined to operate as for femoral rupture. At

9, P.M., a transverse cut was made from the middle of the firm swelling inwards, nearly to the spine of the *pubes*, and a second at right angles with and below it. The other coverings were then divided in the usual way, and on opening the hernial sac, a little dark-coloured *serum* escaped; and when it was fully divided, forthwith a quantity of *omentum* burst through the aperture, and the swelling in the *labium* at once subsided. This portion of *omentum* was very soft and loose in texture, and had been, doubtless, that last descended; but the remainder, forming the bulk of the swelling, was firm and matted together, and upon raising it a knuckle of intestine was seen, dark-coloured but bright and œdematous. Having introduced my finger into the sac, I could not at first pass it down to the stricture, as it was intercepted by a band, which I supposed to be an old adhesion; but having drawn the *omentum* and gut to the outer side, I was enabled to reach, and found the stricture very tight, and admitting only the tip of the finger, but sufficient to allow the entrance of the blunt-ended bistoury, with which I divided, till my finger would pass into the belly, up to the second joint. I then readily emptied the gut, and attempted to return it, but could not succeed. It was thought that the difficulty depended on the stricture not having been sufficiently freed, and I therefore prepared again to introduce the bistoury, by drawing the *omentum* and intestine to the outer side. This, however, being done, a broad membrane was seen descending from the upper part of the sac, behind which the finger could be passed. It was this, doubtless, which first prevented the introduction of my finger into the stricture, and subsequently obstructed the entrance of the gut into the belly by dropping against the mouth of the sac. We determined on its division; and this done without further dilatation of the stricture, the intestine easily returned. The *omentum* was partially adherent to the mouth of the sac, and being in rather large quantity, and its matted part rather bruised, the greater portion of it was removed, and three little vessels in it disposed to bleed were singly tied. The sac having been thus emptied, was found to be of large size, extending rather more outwards than usual; and on its inner side, the finger being pressed, readily passed inwards, and for an inch and a half downwards into the right *labium*; but whether this part of the cavity had any peritoneal lining, I did not observe. She recovered without any drawback.

In January, 1842, she again came under my care with symptoms of strangulation. She had constantly worn the truss, but not to much purpose, as the rupture has come down four or five times a week. The original femoral swelling had now increased to the size of a large fist, and filled up a considerable part of the inguinal region both below and above Poupart's ligament. On its inner side, the part which had descended into the *labium* was also enlarged, and its fore and upper part had assumed a remarkable form, exhibiting the appearance of the *appendix auriculæ* of the heart, with its loose extremity projecting upwards and forwards. This labial part of the swelling was very hard and firm, and its contents seemed solid, whilst the outer and larger portion was evidently filled with intestine, which could be readily felt, as the skin alone appeared to cover it, and pressure caused much gurgling.

The rupture was returned, after the warm bath, by emptying the smaller into the larger swelling, which having been done with some difficulty, the aperture between the two was grasped tightly, so as to prevent any escape, the larger swelling being thrust into the thigh by an assistant. I again employed the *taxis* upon it, and the rupture was slowly but completely returned into the belly. The mouth of the sac was large enough to admit the entrance of two or three fingers, and through the inside, the fingers could be readily passed into the appendicular swelling, and to the bottom of the *labium.*—J. F. S.]

1228. Wounding the epigastric or obturator artery, or one of their branches, in the operation for inguinal or femoral rupture, may cause a fatal or alarming bleeding, the more, as the blood is commonly poured into the cavity of the belly. By proper consideration of the points mentioned in the several kinds of these ruptures, this injury may indeed always be prevented. For stanching the bleeding, compression with oak agaric, plugs of lint moistened with styptics, with peculiar instruments, (Desault, by means of broad compressing forceps, Schindler, with forceps having a hinge, Hesselbach, with a peculiar compressor, Hager, with the compressor for the middle meningeal artery,) the passing a needle around the bleeding vessel, the enlargement of the incision, and special tying the vessel, have been proposed. Hesselbach's instrument (*a*) seems to have the preference; with its spoon-shaped part we must endeavour to find the seat of the bleeding, as when it is passed into the belly, the blood in that cavity escapes externally, which, however, is better done by introducing the forefinger. The spoon-like part is then to be placed on the wound of the vessel, the other broad part, on the front wall of the belly, and by means of a screw, the two parts are to be pressed together. A cold application assists the operation of this remedy.

[Although it cannot be doubted that wounds of either the epigastric or obturator arteries are very dangerous accidents, yet it is very remarkable that with the frequent variety of their origin and in the great number of operations for strangulated rupture, such cases are exceedingly rare, the number collected by Lawrence being not more than twelve or fourteen. In one of these, "the epigastric artery had been completely divided at three quarters of an inch from its origin, and it did not appear that the smallest quantity of blood had escaped from the divided vessel;" in another, in enlarging the stricture, "the wound immediately filled with arterial blood, which rose again almost directly to the edges of the incision when removed with the sponge. * * * The patient lost about a pint of blood, fainted, and the bleeding ceased, nor did it come on again." (p. 271.) In other cases, however, the patient died of the bleeding, either with or without the mischief having been discovered.

If there be reasonable ground to suppose that either artery is wounded, the proper proceeding is to seek for and tie it, which was done by Mackay with success (*b*).

It is also remarkable that the bleeding does not always come on immediately at the operation; but from the two following cases it appears that this may arise from other

Ein Anhang und Beitrag zu den neuesten anatomisch pathologischen Untersuchungen über die Leisten und Schenkelbrüche. Würzburg, 1816; with two copper-plates.

(*b*) A. Cooper, p. 41.

arteries than either obturator or epigastric. **Lawrence** mentions a case of strangulated bubonocele in which "no blood was shed during the operation; hæmorrhage, however, took place on the same evening, but yielded to the application of cold cloths." There was no further bleeding till "the morning of the eighth day, when a profuse hæmorrhage took place from the wound; it consisted of arterial blood, and did not cease till two pints at least had been lost. He survived this occurrence about a week." The vessel which had been divided was "the arterial branch, which the epigastric sends to the spermatic cord; but its size did not seem adequate to the supply of so profuse a bleeding." (pp. 273, 74.) **Everard Home** (*a*) also relates a case of strangulated scrotal rupture, in which suppuration of the testicle having followed the operation, "a hæmorrhage took place in the evening (of the tenth day), which made the removal of the testicle necessary in order to secure the vessel. He lost a pound of blood;" but ultimately recovered. (p. 109.)]

III.—OF UMBILICAL RUPTURE.

1229. The *True Umbilical Rupture* passes through the opening of the navel, and is thereby distinguished from the so-called *false umbilical rupture*, which is formed in the neighbourhood of the navel. Umbilical rupture, is either *congenital*, or *arises accidentally* after birth.

1230. Congenital Umbilical Rupture is the consequence of an arrested development of the *fœtus*, of a backward formation of the abdominal muscles, the *fœtus* remaining in that earlier stage of development, in which the intestines have not yet entered into the cavity of the belly. This rupture is situated in the spongy cellular tissue which connects the vessels of the navel-string together. It is therefore on this account opaque, where covered by the integuments of the belly, but transparent over the rest of its extent where surrounded by the cellular tissue of the navel-string. Besides this cellular tissue, this rupture is also enveloped in a hernial sac, and lies in a triangular space, which is produced by the separation of the vessels of the navel-string from each other. The veins are always above, the two arteries below and on the sides. The size of this rupture varies according as it contains a larger or smaller quantity of intestines. Several portions of the small intestines are usually contained in the swelling; frequently, also, the *colon*, *omentum*, stomach, liver, and spleen.

• [In tying the umbilical cord after birth, care should be taken to ascertain previously whether there be any protrusion of *viscera* into it, which sometimes having, from the small size of the rupture been overlooked, intestine has been included in the ligature, and wounded; instances of which are mentioned by **Mauriceau** (*b*), **Sabatier** (*c*), and others. —J. F. S.]

(*a*) Cases and Observations on Strangulated Hernia, in Trans. of a Society for the improvement of Med. and Surg. Knowledge, vol. ii.

(*b*) Traité des Accouchemens, vol. i. p. 497.

(*c*) De la Médecine Opératoire. vol. i. p. 152.

1231. Umbilical rupture after birth occurs, from the time of the separation of the navel-string to the third or fourth month. If circumstances, as violent screaming, restlessness of the child, and the like, then operate, which force the intestines violently against the walls of the belly, a portion of *peritoneum*, and of intestine, is easily thrust through the still open navel-ring, or the scar, not yet firm, gives way.

As the navel, after the proper obliteration of the *annulus umbilicalis*, must be considered as the firmest part of the abdominal wall, it is probable that in the cases where true umbilical rupture has been observed in adults, it had already formed in childhood, but, on account of its small size, had been overlooked; or that the navel-ring is enlarged, as a consequence of great extension of the abdominal wall, in fat persons, or after frequent pregnancies. Umbilical rupture, in adults, is, therefore, more frequent in women, who have been often pregnant, after great extension of the belly from dropsy, and in very fat persons. Umbilical rupture occurring after pregnancy, has a round, sometimes cylindrical, sometimes conical form, and a circular base; in large swellling, the scar of the navel is more or less smoothed. The coverings of this rupture are:—1, the external skin; 2, the delicate *aponeurosis*, which spreads over the external surface of the abdominal muscles; 3, the *peritoneum* lengthened into the hernial sac. The latter is often very thin, and more often, adherent to the coverings and to the intestines, especially at the point of the swelling; it seems also deficient, and is sometimes torn. The neck of the sac is always very short, and connected internally with the aponeurotic navel-ring; in old and large umbilical ruptures it is tough, and often cartilaginous. In such ruptures, very considerable adhesions exist between the protruded intestines, themselves, and the hernial sac, so that they form an inseparable mass, and the contained intestines can only be returned with difficulty. Collections of stool may therefore occur in that part of the intestine between the rupture and the navel, vomiting, and the like. Actual strangulation is rare in umbilical ruptures; if, however, it occur, the symptoms are more severe than in other ruptures, and more rapid mortification is to be dreaded.

[ASTLEY COOPER mentions "an example of the sac having been either absorbed or burst, by which openings have been formed, and portions of *omentum* protruded through the sac of the larger one."

Sometimes an umbilical rupture forms two tumours, of which ASTLEY COOPER mentions an instance operated on by the elder CLINE, who, "after returning the intestine from the hernial sac, on putting the finger into the *abdomen*, an opening could be felt about half an inch from that by which the finger passed, which led into another tumour by the side of the former." (p. 31.) On *dissection*, in the tumour that was most inferior "I found," says COOPER, "a small portion of the *ileum*, and part of the *cæcum*. In the other tumour there was a portion of *colon*, and which adhered to the sac." (p. 47.)

I have had a case (No. XI. in the Table) somewhat similar, in which the rupture, about the size of a half-quartern loaf, had somewhat the shape of the figure 8, the head of which was rather smaller, and bent over to the left side. In the course of the operation a deep tough band of cellular tissue was found thrusting down the middle of the hernial sac, which retained the indentation after the cellular band had been cut through. The sac contained a large quantity of hard impacted *omentum*, and some inches of intestine. —J. F. S

Umbilical Ruptures sometimes acquire "enormous size in women, whose bellies are pendulous, from bearing a great number of children. In three such instances," says COOPER, "I have seen the *hernia* extending so low from the navel as entirely to cover the *pudendum*;" the largest he ever saw "measured across twenty inches by seventeen." (p. 34.)]

1232. In congenital umbilical rupture, it depends on its size and on the condition of the walls of the belly, whether anything can be undertaken for its cure. If that part of the intestine, external to the belly, be not large, and be reducible, its return must be carefully effected and reprotrusion prevented, by graduated compresses, which should be fastened with strips of sticking plaster and a body-belt. This practice is preferable to that followed by Hamilton, who after returning the intestine, applied a stout bandage around the base of the swelling, and brought the edges of the abdominal coverings together, with two silver needles and sticking plaster, and the cure was effected in a few days (*a*). If the congenital rupture be considerable, and its return in a gentle manner not possible, the child usually dies soon after birth, in which case, the external covering of the swelling is thrown off and the intestines are laid bare. Experience, however, proves, that if the swelling be properly protected from all external pressure, granulations may be produced after separation of the external covering, and thus the whole part be gradually covered with firm skin and a tendinous expansion (*b*).

1233. The *treatment* of umbilical rupture occurring after birth, is easy. The parts are returned without difficulty, and are kept up with a convex pad of wood, wax, or the like, applied close to the navel-ring, and properly fastened with sticking plaster, and a broad bandage. In changing the dressings, especial care must be taken that the protrusion of the intestine be prevented, by pressure of the finger on the navel-ring, till the pad be again properly applied. Usually, in children, a radical cure very soon takes place, on account of the natural tendency of the navel-ring to obliteration. In adults, elastic trusses, which yield to the motions of the abdominal muscles, are employed. Of the many, and some very complicated umbilical trusses, an elastic truss of a similar kind to that for inguinal rupture is preferable, of which the spring should be well fitted to the fulness of the belly, and its pad project directly from the spring; or a somewhat concave metallic plate, to which is attached a spring, with a pad, and kept in its proper place by an elastic bandage attached to both sides of the plate; or a plate of horn is applied, in the middle of which is screwed a pad, and fixed with a large, tight, sticking plaster, and a belly-band, by which the rupture can be most certainly kept up. If the rupture cannot be returned, a large hollow pad must be used, by which the increase of the rupture is prevented.

Rothmund (*c*) after completely replacing the contents of the hernial sac, presses the external coverings and the hernial sac through the mouth of the sac into the belly, and thrusts a round plate, corresponding in size to the extent of the aperture, into the pouch thereby formed. On this plate, which can be kept steady by a stem projecting in its middle, a contrivance is to be attached, which can increase it from two to four lines at the greatest part of its periphery. By drawing the stem, the enlarged plate, which no longer can escape out of the mouth of the hernial sac, is firmly applied against the inner hinder wall of the latter. A somewhat larger plate, with an opening in its middle, corresponding to the inner plate, is applied on the coverings of the belly, and then the projecting stem of the first is to be passed through the opening of the second, and fastened by a contrivance attached to it. In this way the ensheathed hernial sac may be firmly compressed, at pleasure, at the whole hinder extent of the mouth, to the extent of some lines; and by this gradually increased pressure, after some days, adhesive inflammation is excited, by means of which the mouth of the hernial sac is closed, the compressed parts of the ensheathed sac at the hind surface of the navel-ring becoming adherent to it, and to the umbilical canal. This compressor cannot generally be borne more than three, and at most, five days. If the ensheathed hernial sac look livid, the

(*c*) Müller, above cited, p. 53.

the compressor must at once be removed. The compressors are made of wood and metal (*a*).

["The presence of the intestine and *omentum* in the tumour keeping the navel open, oppose," says DESAULT, "its continual tendency to close; a tendency, however, which sometimes becoming greater than the resistance of the escaped parts, compels their return into the belly, obliterates the aperture which has given them passage, closes, consolidates it, and hence spontaneous cures of infantile umbilical ruptures occur." (p. 317.) He gives two instances of this fact. The one, a female child of two years of age, with a rupture the size of a large nut, which had occurred soon after birth, and for which nothing had been done. He proposed applying a ligature, but the parents would not permit it. In the following year he saw the child again, and the rupture had disappeared. Nothing had been done, but the tumour had gradually subsided. In the other case the rupture had existed from birth, and at five years of age it was determined on applying the ligature. It was however deferred, in consequence of an attack of small-pox. After the child's recovery the swelling was found much diminished, and DESAULT, presuming it might be cured by nature, left it alone. He was right; at the end of eight months it had entirely disappeared. SOEMMERING (*b*) and BRUNNINGHAUSEN (*c*) have mentioned several similar instances.]

1234. If the operation be necessary in strangulated umbilical rupture, the opening must be carefully made into the swelling, because the covering, are often very thin, and the hernial sac adherent to the skin, or intestines, or torn. The cut through the coverings should be made perpendicularly. If after opening the sac, and the proper disentanglement of the intestines, and so on, reduction cannot be effected, a director must be introduced between the neck of the sac, and the navel-ring cut into downwards with the button-ended bistoury. If previous to the operation, the impossibility of returning the rupture, on account of the existing adhesions, should be perceived, if the parts of the rupture be not gangrenous, a semilunar incision is to be made at the bottom of the swelling, on the right or left side, through the skin, the thin *aponeurosis* carefully divided, and a director attempted to be introduced at the upper or under part of the navel-ring, between it and the neck of the sac, and upon it the button-ended bistoury for cutting into the navel-ring; or if this be not possible, the point of the left forefinger, with the nail turned down, is to be placed between the neck of the hernial sac and the under edge of the navel-ring, and upon it a cut with a straight bistoury is to be carefully made from without inwards with a gentle motion of the hand. But if the parts in the rupture be gangrenous or self-strangulated, the sac may be carefully opened at any convenient place. The further treatment is to be guided according to the ordinary rules.

[ASTLEY COOPER mentions "one circumstance of danger which is peculiar to the umbilical *hernia*, which is, that when the skin has become very thin over the tumour, the pressure simply of the protruded parts, under strangulation, will sometimes very early destroy the life of that portion of the integument by stopping the circulation through it. It first turns green, the cuticle then separates from it, and that portion of the skin becomes dry and of a brown colour; and in the instances in which this circumstance came under my observation the patients have died." * * * "Suppuration," he also observes, "now and then takes place in the *omentum* of an irreducible umbilical *hernia*." (p. 35.)

As pregnancy is not an unfrequent cause of umbilical rupture, it is rather curious that strangulation at this period so rarely occurs. If it cannot be overcome by the usual remedies, the operation may be resorted to without the patient's condition rendering it less hopeful. ASTLEY COOPER mentions one case operated on successfully in the eighth month of pregnancy (*d*); LAWRENCE one in the seventh or eighth month (*e*); and CLEMENT another in the fourth month (*f*).]

1235. The radical cure of reducible umbilical rupture, in young persons, by the application of a ligature, after the reduction of the intestines, around the integument covering the rupture, by tying which tightly the parts taken hold of are destroyed, and a tough scar formed (1), is generally exceptionable ; because, firstly, umbilical rupture is very commonly cured in children by the mere powers of nature; secondly, because the cure can certainly be effected by continued moderate compression; thirdly, because the operation is very painful, even dangerous, (as a small part of an intestine may be included in the ligature,) and after the scarring of the suppurating parts, compression is necessary for a much longer time; fourthly, because no decided radical cure can be effected, as a part of the neck of the hernial sac always still remains, and the scar produced is not sufficiently firm to prevent the dragging of the intestine. In female children, it must also be remembered that in pregnancy the scar may be torn (*a*). But in all the umbilical ruptures, which are several inches long, and purse-shaped, if the firm application of a truss be prevented by the great lengthening of the skin the ligature may be proper; and if it do not effect the closing of the navel-ring, the close application of a truss may be rendered possible (*b*).

(1) In former time this was recommended and practised by Paulus Ægineta, Albucasis, Paré, and others; objected to by Guy de Chauliac and Dionis, and again recommended, especially by Desault (*c*), von Gräefe, and others.

[Scarpa, Astley Cooper, and others, are much opposed to the ligature. Benedict of Breslau has also abandoned it on account of the serious, if not dangerous, symptoms resulting from its use. He says (*d*):—" In all the cases, pain in the belly came on about the third day, with great tenderness to the touch, especially near the navel, and considerable fever, so that the presence of peritoneal inflammation could not be mistaken; in one instance there was also vomiting. All the patients recovered under antiphlogistic treatment; but the symptoms were so formidable for two days, that a Surgeon would not be justified in employing this treatment unless all other measures had failed." And its my opinion he would not be justified even then ; for it is asserted by Richerand (*e*) than many of Desault's cases, supposed to be cured, returned. A case is also mentioned (*f*) in which a child of seven and a half years old died in consequence of such treatment, the operation being thus performed; " the patient was placed on her back, the contents of the *hernia* were returned, and the sac was raised and twisted to insure the reduction. A flat buckskin ligature, three-fourths of an inch wide, was applied close to the *abdomen*, not so firmly as to strangulate the parts, but sufficiently to retain the *viscera* and excite adhesive inflammation in the sac. A strong silk ligature was then applied with sufficient firmness to interrupt all circulation. When the mortified part was cut away, it was found that a portion of *omentum* had adhered to the sac, and of course had been included in the ligature. The patient died on the tenth day. The ring was perfectly closed by adhesion and granulation, which sprung from its tendinous margin ; the *colon* adhered to the inner surface of the granulations; no inflammation could be detected in any part," (p. 368.) It must be admitted that in this case circumstances were not very favourable as to the success of the operation. " The mouth of the sac presented a diameter of three inches, and the enormous tumour extended to the knees. The swelling measured at the neck twelve inches in circumference; six inches lower it was fifteen inches; it was seventeen inches in length ; and two extensive ulcers existed on it posterior surface" (*g*).—J. Cooper Astley, above cited, part ii. p. 49.

1236. A *Ventral Rupture* is that which protrudes through an unnatural opening on the front or side of the belly. This rupture is much more rare than either of those already mentioned. It takes place through openings in the abdominal muscles, and their *aponeuroses;* most commonly in the space between the two *m. recti*, more rarely on the sides of the belly, from the hip-bone to the last rib, and in the lumbar region (*Lumbar Rupture*) (1).

The *causes* of this rupture are the ordinary occasional causes of rupture, with existing relaxation of the abdominal walls, especially of the white line, after many pregnancies, in quick emaciation after previous stoutness; or it is caused by tearing of the muscles and *aponeuroses*, at the parts where scars have formed (2). Or the entire walls of the belly often spread into a sac which contains intestines (3). These ruptures are generally provided with a hernial sac, except when they are consequent on previous wounding of the *peritoneum*.

[(1) Of this very rare form of Ventral Rupture Cloquet gives an instance in a man of seventy-five years, who, whilst lifting a heavy mattress, felt a violent pain, with a sense of tearing in his loins, which gradually subsided in course of six weeks. But about a fortnight after, whilst getting up in his bed, he had a fresh attack of pain at the same spot. When seen next day he was much agitated, had violent colic, some *nausea* and vomiting, and his bowels were costive. The skin in the right lumbar region, without being discoloured, was raised slightly by a rounded swelling about five inches from the spines of the *vertebræ*. It was little tender, and when grasped, was found to be somewhat elastic, crackling, deeply situated, or at least separated from the skin by a layer of fat. It had a broad pedicle, increased in bulk, and dilated on coughing, sneezing, and making water. He had severe and constant pain deep in the right lumbar and iliac regions in the course of the *cæcum* and ascending *colon*. The swelling was much larger when he stood up than when lying down, and when he turned on his face it disappeared, and left a hollow readily distinguishable by the touch. He was treated by putting a pad upon the seat of swelling, after its contents had been returned, and confining it with a circular bandage. (pp. 5, 6, *note*)

(2) I have seen two or three cases in which, after pregnancy, the *linea alba* has been torn to the extent of several inches; and in one of them below the navel I well recollect I could, without difficulty, bury my whole hand in the cavity of the belly, thrusting in the skin as a large pouch before it. In neither of these cases, however, was the protrusion of the bowels very considerable. There did not seem to be anything remaining but the skin alone.—J. F. S.

Lawrence mentions a very interesting case of a woman who strained herself by lifting a heavy table, and died from inflammation of the chest. She had complained only of pain in the loins. But on examination both *m. recti abdominis* were torn through about one third of their thickness, and there was a small quantity of coagulated blood about the torn fibres; but the sheath was not ruptured. (p. 583.) Probably, had she lived, this would have become a ventral rupture. In reference to wounds of the belly, which are sometimes followed by ruptures, he mentions, as an example, that this does not always occur. The case of a boy who had been largely gored by the tusk of a boar, and had the greater part of the stomach distended by a hearty dinner recently taken, the *omentum,* the transverse arch of the *colon,* and some small intestines protruded through the wound; they were returned with difficulty, and having been retained by the uninterrupted suture the case did well, and no rupture followed. (p. 584.)

(3) Of the latter kind, in which a portion of the entire abdominal wall seems to yield, various instances are mentioned. Richter describes a broad swelling, as large as a woman's breast, in each groin of the same person (*a*). And Siebold describes one equal to a loaf of bread in size, between the cartilages of the ribs and navel (*b*).]

1237. These ruptures may happen through the whole length of the white line (*Herniæ lineæ albæ*); but they are more commonly observed in that part above the navel, than in that below it. They for the most part contain a portion of *omentum;* if they be below the navel there usually lies in them a small piece of intestine, frequently the bladder or the womb. They often protrude so near the navel as to be easily mistaken for umbilical rupture. They have always an oval form, and have little prominence in comparison with their size; their neck is always oval, like the cleft through which they have passed; the neck of the sac is always very narrow in comparison to its size. If quite close to the navel-ring, they are distinguishable from true umbilical rupture by the oval shape of the neck of the sac, and by the navel being seen on one or other side of the swelling. Ruptures in the white line happen most frequently in women; their coverings are the same as those of umbilical rupture. They are kept up by the same trusses as the latter; but their radical cure is by far more rare than that of umbilical rupture. If there be strangulation, and the operation be necessary, it is the same as that for umbilical rupture; only the opening into the belly is best enlarged on one side or other.

1238. From these ruptures of the white line must be distinguished, those swellings formed by a portion of fat which has penetrated through a cleft in the white line, and have great resemblance to the omental ruptures of the white line. These swellings feel hard, are insensible, irreducible, and produce no inconvenience. If such swelling be accidentally accompanied with colic, a mistake is very easy. (Compare *par.* 1203.)

1239. At the upper part of the white line, and on the left side of the ensiform process, little ruptures not unfrequently arise, which, on account of the severe irritation of the stomach connected with them, may be called *Stomach Ruptures, (Herniæ ventriculi, Gastrocele,)* but they usually contain a part of the transverse *colon* (*c*). They are often so small as to be scarcely perceptible, have usually the size of an olive, and are rarely larger. They produce, without being strangulated, pain, dragging at the stomach, great tenderness of the pit of the stomach, vomiting, hiccough, *nausea,* especially after eating; and these symptoms diminish in the supine posture. The swelling is only felt when the patient stands up, or when the body is bent forward. The cleft through which the rupture protrudes may be, perhaps, felt in coughing. For the purpose of keeping up this rupture, it is best to wear stays made of whalebone, which, at the part corresponding to the rupture, are furnished with a pad of sufficiently large size.

1240. The *treatment* of the other Ventral Ruptures agrees, except in some slight modifications, with that for ruptures of the white line. If

strangulation render the operation necessary, the dilatation of the stricturing part must be made in such direction that no important vessel shall be injured, and as much as possible directly upwards.

V.—OF ISCHIATIC RUPTURE.

(*Hernia ischiatica, dorsalis, iliaca posterior,* Lat.; *Hüftbeinbruch,* Germ.; *Hernie ischiatique, Ischiocèle,* Fr.)

1241. *Ischiatic, Dorsal Rupture*, passes through the notch of the haunch-bone, above the sacro-ischiatic ligaments and pyriform muscle, below the gluteal muscle, and appears externally near the lower part of one of the lateral edges of the rump-bone, or *coccyx;* it attains often a considerable size, extending more either upwards and backwards, or outwards, towards the *perinæum.* It contains, either merely intestines, urinary bladder, or both small and large intestines, the womb, and the like, together. It is undecided whether the male or female sex be more subject to this rupture. It is more frequently noticed on the right than on the left side. It may be congenital, or may occur subsequently.

The various cases of this rupture described are those of—

Hager, above cited, p. 275.

Roubein, Annales cliniques de Montpellier, vol. viii. p. 354.

1242. The *diagnosis* of this rupture is very difficult. Whilst it is small and covered by the great gluteal muscles, it cannot be discovered. In making the *diagnosis*, we must first remember the seat of the swelling; the suspicion of a rupture is so much the greater when it is congenital, and has a form, namely, a globular form, which other swellings generally have not. It can only be determined when the intestine can be felt in the rupture, which may be returned, and again protrude. In small ruptures the convolutions cannot be at all felt; and even without adhesions, the return of this rupture may be impossible, on account of the small size of the aperture by which it has escaped. In large ruptures, an emptiness of the belly is noticed.

Congenital ischiatic rupture first begins with a broad base from the body, but in larger ones the neck is narrower than the bottom. As the urinary bladder can alone lie in dorsal rupture, so must the symptoms of vesical rupture be remembered in the *diagnosis.* The distinction of this rupture from a fatty or encysted swelling is difficult; it may be easily mistaken for an abscess when it proceeds to suppuration. *Spina bifida* is distinguished from this rupture by its seat in the middle of the rump-bone, by its fluctuation, and, in most cases, by its transparency.

1243. As in this rupture the pelvic *aponeurosis* is ordinarily torn and not displaced with it, it is covered only by skin, and by the outspread, or divided fibres of the *m. levator ani.* The sac of the rupture lies between the under inner edge of the great gluteal muscle and the side of the *rectum.* On the inner side of the hip-bone, the neck of the sac is immediately surrounded by the obturator artery, both above and below. Upon the outer side of the hip-bone, the ischiatic nerve lies before and below, and the gluteal artery behind (A. COOPER) (*a*).

1244. Small dorsal ruptures may be easily reduced; they return of themselves into their proper place. Large and more long-continued ruptures are capable of a slow reduction by a continued suitable position and external pressure. Reduction may be impossible on account of adhesion, or if the greater number of the abdominal organs be contained in the rupture, on account of the contraction of the walls of the belly. According to ASTLEY COOPER, if ischiatic rupture render the operation necessary, and the extension of the mouth of the sac cannot be effected with a blunt hook, it must be divided forwards. SEILER considers it absolutely necessary in dividing the mouth of the sac, to cut layerwise from without inwards, and to tie the divided arteries immediately.

HAGER (*b*) distinguishes an *upper* and *lower* ischiatic *rupture;* the one should descend above the *m. pyriformis,* the other between it and the ischiatic nerve and the upper of the *m. gemini;* the one has at its escape from the ischiatic hole the upper gluteal artery above and behind, and the nerve below it; the other has the lower gluteal artery, the pudic artery and vein, and the nerves below it. It is best not to open the hernial sac, and in the superior ischiatic rupture, to divide its mouth forwards and outwards, but in the inferior, forwards and upwards.

SCARPA (*c*) considers this in women as enlarged pudic rupture, and in men as large perineal rupture, and therefore treats them as such. This opinion is perhaps right as regards some of the above-described cases, for instance, those of PAPEN and BOSE; but it is contradicted by other cases in which there has been sufficient anatomical examination.

VI.—OF THYROID RUPTURE.

1245. In *Rupture of the Thyroid Hole*, the intestines pass through the opening in the ligament by which the obturator nerve and vessels pass The share-bone is in front of the neck of the sac, and its under, inner, and outer part, is surrounded by the obturator ligament. The base of the

---

(*a*) Above cited, pl. xxiii.

(*b*) Above cited, p. 272.

(*c*) Supplement, above cited, p. 150.

rupture is between the *m. pectineus* and *adductor brevis*, or between the front heads of the *adductor*. The obturator vessels are upon its inner hinder part, and large branches of the obturator nerve are before it. Differences however may occur, especially if the obturator and epigastric arteries arise in common, of which a case was seen by GADERMANN where the artery passed first on the inner, and then on the front of the hernial sac. This rupture is at first very apparent, if a large quantity of intestine be protruded. It may have a different form, because it penetrates through different interspaces of the muscles. It occurs more commonly in females than in males, and may contain intestines, *omentum*, and even the urinary bladder; and not rarely does it occur at the same time on both sides.

[CLOQUET says (*a*), that " Ruptures of the subpubic (thyroid) hole are much more frequent than generally supposed, and that they are more commonly met with in women than in men. They have distinctive characters when they have attained a certain bulk; are capable of being operated on, especially in thin persons; and that the bladder may displace itself, through the subpubic hole " (p. 87.) In a case, however, which he has given an account of (*b*), the tumour produced no visible external swelling, although of the size of a small hen's egg : but it was covered by the *m. pectineus* and *adductor longus*. And in DUVERNEY's case (*c*), in which there was rupture through both thyroid holes, although each of the swellings was as large as an egg, yet no external tumour was observed. Neither was there any swelling in SMITH's, of Manchester, case (*d*). It must, therefore, be taken as a rule, that these ruptures are not usually discoverable, although in GARENGEOT's patient it was; the tumour, which was distant about a finger's breadth from the *pudendum*, descending six inches down on the inner and upper part of the thigh (*e*); it was reduced. LAWRENCE considers that " the *m. pectineus*, the long and middle heads of the *m. triceps*, and the *m. gracilis*, so completely close the space into which the sac protrudes, that they must by their pressure prevent it from increasing to any great bulk." (p. 619.)

FRANTZ relates (*f*) the case of a woman, forty years old, who, with many symptoms of strangulated rupture, had severe pain at the upper inner part of the left thigh, which came on suddenly, and recurred every ten minutes. No swelling was observable, but pressure high up between the *m. triceps* and the adductor muscles produced severe pain. There was neither tenderness nor pain in the belly. Three years previously she had had the same symptoms, but was suddenly relieved, whilst pressing on the part, when something seemed to go back with a noise into the belly. This had occurred more than once since, though less severely. When FRANTZ attended her, the symptoms were much more violent and less manageable; bleeding, purging, pressure, and other means were useless. Stercoraceous vomiting occurred on the ninth day, and the symptoms of strangulation increased up to the fourteenth, when she seemed dying, but a free discharge of stool then took place; and ultimately she recovered.

The only two examples of this disease I know of, are one from a male subject in St. Thomas's Museum, and another in the collection of the Royal College of Surgeons.—J. F. S.]

1246. The *diagnosis* is founded on the seat of swelling at the upper inner part of the thigh, on its peculiarly elastic tension, on the mode of its origin, on the possibility of its reduction, on the sensation of gurgling, or of different kinds of contents in the swelling, and on the gastric symptoms which usually accompany ruptures. This rupture may be strangulated, and the strangulation is usually at the mouth of the sac, but is more rarely caused by the neck of the sac or by the muscles.

1247. If the rupture be reducible, it must be returned to its proper place, and there retained by means of a graduated compress and an inguinal spica bandage, or with an inguinal truss, of which the neck is

more lengthened downwards, and the pad comes directly below the transverse branch of the share-bone, at the origin of the *m. pectineus*. If there be strangulation, if the remedies employed be ineffectual, and the operation be indicated, the enlargement of the stricture, when possible, must be effected in the bloodless way, with the blunt hook from within outwards, and downwards. The dilatation with the knife, if necessary, must, according to Astley Cooper, be made inwards.

If the rupture be concealed beneath the muscles, the *diagnosis* is rarely so certain that the operation can be undertaken. According to Gadermann (*a*), the cut must be made through the skin and femoral ligament, an inch below Poupart's ligament, and as far from the pubic *symphysis*, and continued rather inwards, about four inches in length; the pubic muscles must be cut through obliquely, and also the long and short heads of the *m. triceps*.

VII.—OF VAGINAL RUPTURE.

(*Hernia vaginalis*, Lat.; *Scheidenbruch*, Germ.; *Hernie vaginale*, Fr.)

Stark, Dissert. de herniâ vaginali et stricturâ uteri. Jena, 1796.

Cooper Astley, above cited, part ii. p. 56.

1248. In *Vaginal Rupture* the intestines pass down in the fold of the *peritoneum* between the womb and the *rectum*, or between the former and the bladder, in consequence of which a swelling takes place on the hinder or front wall of the *vagina*, but for the most part more on one than on the other side, which, as it enlarges, passes between the *labia*, and attains considerable size. The rupture usually contains the urinary bladder when it is on the front wall of the *vagina*, or the womb when it is on its back wall. There may be also a portion of the small intestine, more rarely of the *colon* or of the *omentum*. The swelling is elastic, and free from pain; when pressed it recedes, but recurs on coughing, and so on; it increases in the upright, and diminishes in the supine posture. The mouth of the womb is completely free. If the swelling occur at the hind wall of the *vagina*, it is generally deeper than in front; in the latter case it is also usually accompanied with great inconvenience, in consequence of displacement of the bladder. With a large rupture at the hinder wall of the *vagina* there is most commonly prolapse of the *anus*. If the rupture be caused hastily, by violent straining and the like, the patient feels as if something were torn in the *vagina*, and severe pain, which subsequently is converted into a remitting colicky pain. If the vaginal rupture contain the bladder, it causes great disposition to make water, itching in the *urethra*, retention of urine, tension and painful distension of the belly, sometimes agitation, restlessness, dragging at the stomach, and sundry disturbances of the nervous system. In the protruded part of the bladder a stone may be formed.

1249. The predisposing causes of vaginal rupture are, relaxation of the *vagina* from previous delivery; whites, improper use of *coitus*, warm bathing, fire-pans, relaxed state of the body, inclination of the *pelvis* backwards, so that the intestines sink more deeply into it, and also wide *pelvis*. This rupture generally occurs soon after delivery, from straining; it rarely happens in unmarried women.

(*a*) Above cited, p. 29.

1250. The replacement of vaginal rupture is usually easy. The patient being placed on her back, pressure is made with the fingers upon the swelling, and continued, if it return upwards with the fingers, even to the entrance of the womb. If the reduction be difficult it should be favoured by relaxing clysters, and by continuing the supine posture. The reprotrusion of the rupture is best prevented by a cylindrical pessary, which can be fixed with a T bandage. The patient must avoid all straining, and if the rupture protrude in spite of the pessary, that instrument must be removed, and after the reduction of the rupture, replaced. A radical cure may perhaps in many cases be effected by the continued use of the pessary and of astringent injections into the *vagina*. If this rupture protrude during childbirth, it must be kept back by continued pressure, till the child's head have descended, and then delivery is quickly completed. Vaginal rupture may be strangulated (although rarely, on account of the yieldingness of the parts surrounding the rupture) by the enlarged womb during pregnancy, or by the collection of fæcal matter. The return is effected by the use of suitable means, at least no case is known in which the operation was necessary, which also is only possible when the rupture is low down in the *vagina*.

The midwife RONDEL (a) recommends a ring-pessary of watch-spring and Indian rubber for keeping up this rupture.

VIII.—OF PERINÆAL RUPTURE.

(*Hernia Perinæi*, Lat.; *Mittefleischbruch*, Germ.; *Hernie du Périnée*, Fr.)

1251. *Perinæal Rupture* occurs by the descent of the intestines between the *rectum* and *vagina* in women, and between the *rectum* and bladder in men. The external swelling in the *perinæum* is different; it presents itself in the male generally in the region of the neck of the bladder; in women between the *vagina* and *anus*, usually on one or other side, and at the bottom of the *labium*. This rupture may contain a part of the intestinal canal, of the *omentum* or of the bladder. In women it must always be complicated with vaginal rupture (1). In men it causes various urinary inconveniences.

(1) CHOPART and DESAULT (b) believe that perinæal rupture in women is not possible, as a vaginal rupture is more easily formed. Its existence in women has, however, been proved by the observations of MERY (c), CURADE (d), SMELLIE (e), and SCHREGER (f); and many examples of it have been given by CHARDENON (g), PIPELET (h), BROMFIELD (i), SCHNEIDER, SCARPA (k), JACOBSON (l), and SCHOTT (m); also A. COOPER (n).

1252. Perinæal rupture is rare, and only possible in violent driving of the intestines downwards; in great resistance of the coverings of the belly, great relaxation of the peritoneal fold between the *vagina* and *rectum*, or between the *rectum* and bladder, and in slight inclination of the *pelvis*. Perinæal rupture which contains the bladder, occurs especially in pregnancy, when the bladder is thrust downwards and outwards by the distended womb (*a*). In men, perinæal rupture has a round or pear-shaped form; the swelling is in the *perinæum*, on one side of the *anus*, so that the *raphe* is pressed somewhat aside. In women, so long as the rupture remains in the *perinæum*, the swelling is roundish, and bluntly conical-pointed; as it extends into the *labium* it becomes oblong, egg-shaped. Generally perinæal rupture is small, or up to the size of a hen's egg; but it may attain considerable bulk.

(m) Nosologisch therapeut. Betrachtung dreier interessanter Krankheitsfälle, above cited, p. 59. Frankfurt, 1827. 8vo.

(n) Above cited, p. 59.

1253. The return of this rupture is usually easy, and it may be kept back by a bandage, consisting of a spring surrounding the *pelvis*, from the hinder part of which a curved spring descends, and attached to its extremity a conical pad, which being applied directly upon the seat of the rupture, the latter is kept up by the strength of the spring and by an elastic bandage around the thigh. If this rupture be strangulated, and its reduction by suitable remedies impossible, the operation is neither difficult nor dangerous, as the opening of the hernial sac is almost always external to the bottom of the *pelvis*. After opening the sac, a button-ended bistoury is to be introduced between the intestine and the tough edge of the hernial sac, and the strangulation may be relieved by a slight cut from below upwards, obliquely towards the side (SCARPA.)

The opinion, that by pressing back the external swelling, the rupture cannot be completely reduced, is disproved by SCARPA'S observations.

The Pudendal Hernia of ASTLEY COOPER (*b*), the posterior labial rupture of SEILER, is to be considered merely as a variety of the perinæal rupture in women. The intestines descend along the *vagina*, between it and the *m. levator ani*, and form a swelling on the under half of the *labium*. It is distinguished from inguinal rupture, by the upper part of the *labium* and the abdominal ring being quite free. It is felt on introducing the finger into the *vagina*, pressing on the side of that passage, high up.

See SCARPA, above cited, p. 139.

CLOQUET, J.; in Nouv. Journ. de Médecine, vol. i. p. 427.

BOMPARD; in Dictionnaire des Sciences Médicales de Bruxelles, vol. vii. p. 418.

IX.—OF RECTAL RUPTURE.

(*Hernia Intestini recti*, Lat.; *Mastdarmbruch*, Germ.; *Hedrocèle, Archocèle, Hernie du Rectum*, Fr.)

SCHREGER, above cited, p. 136.

1254. In *Rectal Rupture* there is a prolapse of the *rectum*, which contains the portion of protruded intestine. The predisposition to this rupture seems to be slight inclination of the *pelvis*, slight projection of the promontory, and slight curving of the rump-bone.

1255. A rectal rupture may perhaps be inferred, firstly, from the long continuance of the prolapse and its size; secondly, especially if the position of the body show slight inclination of the *pelvis*; thirdly, if the flatness of the upper part of the belly indicate an unnatural deepness of the small intestines; and fourthly, if the swelling of the prolapse be upon the one side of greater size, and at the same time, firmer, more elastic and fuller, than on the other. The *diagnosis* is determinable only by examination; the attempt to return the prolapse gives opportunity for seeing whether there be any motion of the contents, whether, in coughing and so on, the swelling reprotrude; whether the patient experience any colic in the prolapse. These experiments may be without satisfactory result, if there be adhesions in the rupture. An old prolapse of the *rectum*,

---

(*a*) KOSCH, Dissert. de Cystocele perinæali. Regiomont, 1826.

(*b*) Above cited, p 52.

in which there is thickening, enlargement, and so on, has great resemblance to such adherent rupture. Rectal rupture may inflame; there may be even strangulation, by the contraction of the sphincter muscle.

1256. The *treatment* consists in the return of the rupture, and when this is done, in preventing its reprolapse, as will be mentioned in speaking of the rectal prolapse. If the replacement be impossible, the case must be treated as a prolapse of the *rectum*.

X.—OF PHRENIC RUPTURE.

(*Hernia phrenica*, Lat.; *Zwerchfellbruch*, Germ.; *Hernie diaphragmatique*, Fr.)

[Protrusions through the *diaphragm* occur in different ways.

First, Through the natural apertures by which the *aorta*, *vena cava inferior*, *œsophagus* and intercostal nerves pass. These are very rare, and Astley Cooper says he has never seen an instance. Morgagni mentions one, in which the *omentum*, the *duodenum*, and *jejunum*, with part of the *ileum*, ascended by the side of the *œsophagus*, and compressed the heart and lungs into a very small compass (*a*); also another, in which part of the *colon*, a large portion of the *omentum* and the *pancreas* passed through the hole for the intercostal nerve. Fantoni also mentions a case, in which the stomach and part of the *omentum* had entered the chest by the side of the *œsophagus* (*b*).

Second, From malformation of the *diaphragm*, which is more frequent, and is more common on the left than on the right side, and in the muscular than in the tendinous portion of the muscle (1). Macaulay mentions one case, in which the stomach and greatest part of the *pancreas* had passed into the cavity of the left *pleura*; and another, in which the whole liver had entered the right *pleura* (*c*). If the protrusion and the aperture be considerable, the child dies soon after birth. But if the aperture be small, the patient may live for some years; and in the case mentioned by Astley Cooper (*d*), the following symptoms were observed. Oppression in breathing from childhood; and as she increased in years the least hurry in exercise, or exertion of strength, produced pain in the left side, a frequent cough, and very laborious respiration. After great exertion an attack of pain in the upper part of the *abdomen*, with vomiting, and a sensation of something dragging to the right side, and always referred to the stomach. The cessation of these symptoms was as sudden as their accession; after suffering severely for a short time all pain and sickness ceased. These symptoms were of longer continuance as she became older. At twenty-eight years she died, having had symptoms of strangulated rupture for some days before. *On examination*, eleven inches of the great arch of the *colon* was found to have passed through a hole, two inches in diameter, in the left side of the *diaphragm* into the chest, together with a considerable portion of *omentum* (2). These cases generally are unprovided with any hernial sac, the *peritoneum* and *pleura* both seeming to terminate at the margin of the hole. Cooper, however, relates a case, in which there was a sac considerably larger than a tennis-ball in the right side of the chest, consisting of the *pleura* and *peritoneum* united, with its orifice at a small distance from the right side of the ensiform cartilage, where there appeared a deficiency of

---

(*a*) Epist. liv. art. xiii.

(*b*) De Observ. Med. et Anat. Epist. 1714. Epist. xxiii.

(*c*) Medical Observations and Enquiries, vol. i. p. 25.

(*d*) Medical Records and Researches.

fibres in the large muscle of the *diaphragm*. The sac contained the right extremity of the stomach and beginning of the *duodenum*, the arch of the *colon*, and part of the *omentum* (3).

Third, From wounds or laceration of the muscle, which remain during life. This may happen from penetrating wounds with the sword, or by broken ribs being thrust through the *diaphragm*. Sometimes even a blow on the belly, received in a fall, will rupture the tendon of the *diaphragm*. The patient lived five days, and on *examination* the stomach and part of the *duodenum* were found protruded into the left *pleura* (4). (A. Cooper.)

(1) In St. Thomas's Museum there are two specimens of Phrenic Rupture through the left side of the muscular part of the *diaphragm*; in the one small intestines, and in the other part of the stomach has passed into the chest.

(2) This preparation is in the Museum at St. Thomas's. Two other cases are mentioned; one by Clark (*a*), and the other by the younger Monro (*b*).

(3) An instance of protrusion of half the pyloric extremity of the stomach, the whole arch of the *colon* and the *omentum*, through a hole, two inches in diameter, in the left muscular portion of the *diaphragm*, near the *vertebræ*, is mentioned by Leacock (*c*), in a man of forty-nine, who had severe pain of the belly, especially at the pit of the stomach; constant vomiting, with rigors and disposition to syncope on the slightest movement. He died within thirty hours of the symptoms coming on.

(4) A case of aperture through the tendon of the *diaphragm*, by which the stomach, transverse arch of the *colon*, and *omentum* passed into the left side of the chest, is related by Macfadyen (*d*).

XI.—OF MESENTERIC AND MESOCOLIC RUPTURES.

(*Hernia mesenterica et mesocolica*, Lat.)

It might at first sight appear incorrect to describe these as ruptures, because they do not leave the cavity of the belly; but they are as truly ruptures as if they did, inasmuch as they escape from their proper cavity, the reflected *peritoneum*, and are found on its external surface.

The mesentery and mesocolon, each consisting of two layers of *peritoneum*, may have either of these layers naturally deficient, or torn by violence, and thus an opening may be formed, through which the intestines entering, separate the peritoneal layers and form a hernial pouch between them. Astley Cooper says (*e*) that he is unable to determine which of these is the cause of the disease, but is disposed to believe its source is in an originally defective structure. Whether these cases ever present symptoms of strangulation may be questionable. Of the two cases mentioned by A. Cooper, nothing was known, and his presumption of what the symptoms might have been is of little consequence. In the mesenteric rupture, all the small intestines, except the *duodenum*, had passed between the mesentery by a small aperture in its hinder layer. In the mesocolic rupture, the aperture was in the front layer of the mesocolon on the right side, and it contained all the small intestines, except the *duodenum*, a small part of the *jejunum*, and the termination of the *ileum*. Lawrence says (*f*) he has seen an instance of mesocolic rupture in that portion of the mesocolon belonging to the sigmoid flexure of the *colon*; and also refers to Jobert's case (*g*), in which the intestine having passed through Winslow's hole had become strangulated in an opening of the mesocolon.

(*a*) Transactions of a Society for the improvement of Medical and Surgical Knowlege, vol. ii. p. 118.

(*b*) Treatise on Crural Hernia.

(*c*) A. Cooper, above cited, p. 72.

(*d*) Edinb. Med. and Surg. Journ. vol. xix p. 382.

(*e*) Above cited, part ii. p. 73.

(*f*) Above cited, p. 630.

(*g*) Traité des Maladies Chirurgicales, vol. i. p. 522.

It may also be here noticed that **Lawrence** has seen the broad ligament of the wound separated and forming a sac similar to those just mentioned, (p. 630.)

As the disease is necessarily fatal, it has been proposed to open the belly near the presumed seat of the obstruction, and if possible ascertain it. This was done, though without success, by **Dupuytren**; but his failure is attributed to his own wishes in the conduct of the operation having been overruled. The examination after death proved however that his proposal was the correct one (*a*).

XII.—STRANGULATION OF INTESTINE WITHIN THE PERITONEAL CAVITY.

The bowels may become strangulated within the peritoneal cavity, according to **Astley Cooper** (*b*), by passing through apertures in both layers of the *omentum*, mesentery or mesocolon; by adhesions consequent on inflammation leaving an aperture in which a portion of intestine becomes confined; and by a membranous band forming at the mouth of the hernial sac, lengthening by the repeated protrusion and return of the intestine, and at last accidentally entangling and confining it. To these may also be added the adhesion of the *omentum* to the bottom of the hernial sac, which sometimes becoming tense, presses the bowel passing behind between itself and the hind wall of the belly, and preventing the passage of its contents, produces strangulation. Of the two latter forms notice has already been taken (*par.* 1171 and 1177, *note* 1) as being connected with the ordinary descent of ruptures.

Lawrence observes (*c*), " the violence of the symptoms and their rate of progress vary very much in different instances. They sometimes come on gradually, and advance very slowly, the case appearing to be one of mechanical obstruction, and being attended with an almost indolent enlargement of the *abdomen*. In other instances the close pressure of the stricture excites active *peritonitis* and *enteritis*; the inflammatory symptoms are strongly marked, and the case proceeds rapidly to a fatal termination. As the exciting cause of the mischief is not indicated in these cases by any characteristic symptoms, they are considered and treated as examples of ordinary *peritonitis* and *enteritis*. The real nature of the malady is not suspected until it has lasted for some time, and more especially from the combination of obstinate constipation with fæcal vomiting. * * * The disease if left to itself is inevitably fatal," (p. 630).

The subject of Internal Strangulation has occupied the attention of **Rokitansky** of Vienna, and he has divided it (*d*) into three species. *First*. The narrowing or complete obliteration of the canal of a piece of intestine, resulting from the pressure exerted on it at one or more spots, by a smaller or larger portion of intestine or its mesentery, so as to compress it against the opposite side of the *abdomen*. *Second*. The rotatory species, which consists of the rotation of one part round an axis formed by some other part; it includes three subspecies; *a*, the rotation of a portion of intestine round its own axis; *b*, round an axis formed of the mesentery; *c*, where a portion of intestine forms the axis round which another larger portion with its mesentery turns, so as to touch the periphery of the axis at every point. *Third*. This is caused by some peculiar arrangement of parts, the result of original malformation, or of previous disease. These strangulations of the intestine occur in circular or fissured spaces formed, *a*, by fibres or bands of cellular membrane running from one organ to another; *b*, by adhesion of the free end of the vermiform appendix to some spot of the walls of the *abdomen*, or to a portion of intestine

---

(*a*) **Jobert**, p. 581.

(*b*) Above cited, p. 75.

(*c*) Above cited.

(*d*) Medicinische Jahrbücher des Oesterv. St., vol. xix. 1836.—Also in British and Foreign Medical Review, vol. iii. p. 495. 1837.

or mesentery; *c*, by adherent *diverticula*; *d*, by the adhesion of two convolutions at a single point; *e*, by perforations in the mesentery, or by fissures in an *omentum* altered by disease.

The conclusions which ROKITANSKY draws from the numerous cases with which his paper is illustrated are, *First*, That though no age precludes the possible occurrence of internal strangulations of the intestines, yet they are most frequent in the middle and advanced periods of life. *Second*, That for a longer or shorter period before the fatal termination, the patient is attacked by symptoms indicating a strangulation of the intestine. These generally commencing with a sudden cutting pain in the bowels (in some cases proceeding from a determinate point) followed by more or less rapid visible distension of the belly, tympany, constriction of the chest, anxiety, *nausea*, and vomiting, according to the violence and duration of the strangulation, sluggish bowels and long continued costiveness occur, with or without the previous symptoms. Rest, gentle aperients, and favourable positions of the body, mitigate or dissipate these symptoms, but they recur from the original cause, and terminate fatally. *Third*. The course of the affection is not generally very rapid; it seldom destroys the patient before the second day, and frequently runs on for six, eight, or ten days; rarely extends to the third week, and is then interrupted by remissions and seeming improvements. *Fourth*. The disease may be distinguished mostly by the appearance of the patient; by the succeeding attacks; their origin from a determinate cause, and their course; by the intervals of ease between the attacks; by their suddenness and progressive increase after a certain period; and finally, by insurmountable costiveness. ROKITANSKY rejects all medicine, especially purgatives, and proposes the knife as the only means of relief.—J. F. S.]

II.—OF RUPTURES OF THE CHEST.

CHAUSSIER; in Journal de Médecine, par LEROUX. March, 1814.

VERGNE, sur les Hernies des Poumons. Paris, 1825.

1257. *Ruptures of the Chest* are very rare, and no other part than the lungs can easily be contained in them (*Hernia Pulmonum*, Lat.; *Lungenbruch*, Germ.; *Hernie des Poumons*, Fr.) They are either congenital, and resulting from imperfect development of the walls of the chest, or they occur subsequently, by destruction of the walls of the chest, without wound of the general covering; for instance, by extensive fractures of the ribs, by tearing of the intercostal muscles, by severe cough (1), by destruction of the ribs, and so on. After such injuries, the lungs, on account of great extent and mobility, more frequently form ruptures, if they are not adherent to the surrounding parts (2).

[(1) GRATELUP (*a*) describes a protrusion of the lung between the sixth and seventh rib on the left side, which occurred during coughing. The swelling was soft and elastic, an inch and a half long, and three quarters of an inch wide, and was painful at every inspiration. GRATELUP returned it, and applied a pad with a bandage, after which the patient had no more inconvenience, and recovered.

(2) RICHTER says, that "SABATIER told him of a soldier who at the battle of Rosbach was wounded in the chest. The corresponding portions of two ribs which had been shattered by the ball were lost. The opening however closed, but the broad soft scar soon yielded after the cure, and formed a bag which at every breathing alternately sunk and rose again." (p. 4, 5.)]

1258. If a pulmonary rupture occur after any of the just-mentioned occasional causes, a soft elastic swelling is produced, which gradually enlarges, often brings on a painful dragging, which ceases when the swelling is returned. Its enlargement corresponds with the movements of the chest in respiration.

1259. Such rupture may be easily kept back, by means of pressure, but no radical cure is to be hoped for, because the disease is grounded in a solution of continuity of the ribs or intercostal muscles, which cannot be restored.

(*a*) RICHTER's Abhandlung von Bruchen. Edition 1785.

[As the lungs are occasionally found out of their proper cavity in consequence of deficient formation of the chest and other causes, so is also the heart; and this condition, whether it be simply unnatural position within the chest itself, or actual removal from it in a greater or less degree, is called *displacement of the heart* (*Ectopia Cordis*, Lat.). When the congenital displacement is *within* the chest, the heart may be situated either, *a*, horizontally, which is very rare; *b*, vertically in the centre of the chest, as quoted by **Breschet** (*a*); *c*, vertically with its apex upwards and between the lungs, and its base with the large vessels as low as the navel, as in **De Torres**' case (*b*); or *d*, the heart may be more or less to the right side, and its apex pointed in the same direction, or it may be placed completely on the right side, with or without transposition of the *viscera* of the belly, as in **Breschet**'s four cases (*c*). Similar examples have also been noticed by other writers.

When the heart is congenitally displaced *without* the chest, it may be either on the surface of the body, or beneath the skin. Of the former kind **Breschet** speaks of cases "connected with deficiency in the *diaphragm* and abdominal muscles, in which the heart, liver, and stomach, sometimes also the lungs and all the abdominal *viscera* are contained in a sac, sometimes covered only by *peritoneum*, sometimes by an extension of the common integuments, and sometimes occupying the sheath of the umbilical cord, forming a variety of umbilical rupture." (p. 25.) **O'Bryen** has also given an account (*d*) of partial displacement of the heart, consequent on absence of the ensiform cartilage, and part of the *recti* muscles and *diaphragm*, in which a portion of *pericardium*, containing the tip of the left ventricle, preternaturally lengthened, protruded, together with part of the arch of the *colon* immediately beneath the integument. The child lived three months, and the heart appeared to be insensible to the touch. Or the protrusion may depend on fissure, or deficiency in the ribs or breast-bone. Of the *latter* kind of displacement **Ramel** (*e*) mentions a case in a girl of ten years, in whom the heart was placed below the *diaphragm* in the situation of the stomach. **Deschamps** (*f*) relates the case of an old soldier, in whom the heart was found in place of the left kidney. **Breschet** gives an account of three cases in which the heart was found in the neck.

Displacement of the heart *after* birth may occur at any period, most commonly by various kinds of diseases; but **Stokes** has related (*g*) a "case of probable dislocation of the heart from external violence," in which the person having been crushed between a water-wheel and the embankment supporting it, had two of the lower ribs on the left side, the fifth, sixth, and seventh on the right side, and the right clavicle and *humerus* broken. For the first three hours he was completely insensible. He afterwards felt great pain in the right side of the chest, with a sensation as if a foreign body preventing respiration had been introduced into the right lung; the pain was accompanied with violent throbbing and heaving, and it was soon discovered that his heart was pulsating at the right side of the *sternum*. The person himself is quite positive that before the accident his heart beat on the left side, and was the first to notice its altered position. He recovered, and was subsequently able to follow his usual habits of hunting and shooting.

Actual protrusion of the heart (*Hernia Cordis*, Lat. ; *Herzbruch*, Germ. ; *Hernie du Cœur*, ou *Cardiocèle*, Fr.) is very rare, even congenitally. **Chaussier** gives the account of one case, a female infant in whom there was a soft roundish swelling about an inch high, and two and a quarter inches broad at the upper and fore-part of the belly, in which, on the slightest inspection, the form and various movements of the heart and the dilatation and contraction of its ventricles were observed. Its size varied according to the different states of respiration ; when the child inspired, the heart rose and seemed partially retracted into the chest, but when she expired the heart was driven forwards and downwards and the motions of the ventricles were very manifest. The swelling gradually increased in bulk, and enlarged when the child cried, especially when she was held upright; but it became softer and smaller when she was quiet and laid down. Gentle pressure also diminished the size of the swelling. As far as could be ascertained there was a large opening on the left side of the chest, below the edge of the fourth rib; some of the ribs below were deficient at the aperture. The child was well and healthy. **Chaussier** also mentions the case of a soldier, twenty-seven years old, in whom all the breast bone was deficient below the first pair of ribs. The five

following pairs of ribs had no cartilages, but the seventh pair had cartilages, and united with each other at the mesial line. The interspace thus left on the front of the chest was large oblong, and seemed covered only by skin, and all the movements of the heart could be perceived through it: but there was not any protrusion. The man was perfectly healthy, had served several years, and sustained the ordinary fatigues of a soldier's life (*a*).]

Beck; in **Busch**, von **Graefe** und **Ammon**. Encyclopädisches Wörterbuch, vol. xvi. p. 169, 1837, Article *Hernia Cerebri* (*b*).

1260. *Cerebral Rupture* (*Hernia Cerebri*, Lat.; *Hirnbruch*, Germ.; *Hernie du Cerveau*, *Encephalocèle*, Fr.) is a swelling, depending on the protrusion of the brain through an opening in the bones of the skull, and overspread by the external coverings. It is either *congenital*, or *may arise accidentally after birth*; in the former case, the brain protrudes through some place corresponding to the sutures; in the latter, through an opening caused by loss of substance.

[The definition just given of this ailment, which is the true one, shows that the term *hernia cerebri*, as used by English Surgeons, is most improperly employed, inasmuch as the disease which they so name has no resemblance to a rupture or protrusion of the brain from its proper cavity and enveloped in its natural coverings, but is consequent on a tearing through of its investing membranes, and a luxuriant granulating process of the brain itself, for the repair of a direct injury, resulting from external violence, by which that organ has been wounded; or to fill up the deficiency which the ulceration excited by irritation and subsequent suppuration, consequent on inflammation and ulceration of the *dura mater*, set up by *necrosis* of the neighbouring skull-bone, has produced. The *hernia cerebri* of British Surgeons, upon which the best paper is that of **Stanley** (*c*), is, in fact, no brain-rupture at all; it is merely a luxuriant, or so-called "fungous" growth of a brain-ulcer to fill up its cavity, and is nothing more than a neglected active healing ulcer, of which the attempts for its self-cure being too vigorous, assume effectually an unnatural condition, and thus prevent the reparation of the injury they were intended to cure. This state of the brain has been already noticed (*par.* 450, vol. i. p. 425); and it must not be confused with that now under consideration, of which a very excellent account has been given by **Beck** (*d*); nor with the blood-swellings of the heads of newly-born children, which will be noticed hereafter.—J. F. S.]

(*a*) I have extracted these cases from **Hufeland** und **Harles**' Neues Journal der praktischen Arzneikunde, &c., who quote them from a paper of **Chaussier**'s in **Leroux**'s Journal de Medecine, March, 1814; but I cannot find it there, or in the neighbouring volumes.—J. F. S.

(*b*) I have freely availed myself of this excellent article, which is the best I have met with on a subject little attended to in this country.—J.F.S.

(*c*) Cases of Hernia Cerebri, with Observations; in Med.-Chir. Trans., vol. viii. p. 12.

(*d*) Above cited.

1261. *Congenital Cerebral Rupture* is the consequence of an incomplete or retarded formation of the skull-bones, the interspace being filled only by fibrous membrane, through which the brain, when in a diseased state of expansion, as in *hydrocephalus*, protrudes (1). It occurs most commonly in the middle of the occipital bone, in the region of the great occipital hole, or at the posterior fontanel ; it may be, however, at any other part of the skull, where the bones are still separate. It is characterized by a swelling of various size, covered by the integuments of the skull, which are thinned on the top of the swelling and deprived of hair. The aperture, by which the brain protrudes, is irregular, and the swelling, usually fluctuating, can rarely be much diminished by pressure, and recurs when left alone; the edge of the bone is felt at its base, and the swelling has usually some pulsation. The symptoms vary according to the size of the rupture; if it be small, there is generally no particular disturbance, when the swelling is properly protected from external violence. In large cerebral ruptures, there arises from the weight of the swelling, tearing of the brain, and so on, pain which the child shows by slight moans and sighs, and which may be relieved by proper support and covering of the tumour. Children, with large cerebral ruptures, commonly die early, and pass their short life in continual stupefaction ; are often sick, badly nourished, and are frequently convulsed. The swelling may inflame and burst, and the patient then soon dies. Several cerebral ruptures may exist at once. Those affected with cerebral rupture often live long, and frequently, without any disturbance of the bodily or mental powers being thereby caused.

Held (*a*) saw a cerebral rupture, in a girl of twenty years ; Guyenot (*b*), in a man of thirty ; Richter (*c*), in a man of sixty ; Lallemand (*d*), in an imbecile girl of twenty-three years ; Wedemeier (*e*,) in a young man of eighteen, who was small, imbecile, and almost speechless.

On examination of congenital cerebral rupture, the *galea aponeurotica* and *dura mater*, are found tolerably united together beneath the external skin. In the sac formed by them is a large or small portion of brain, covered by the *tunica arachnoidea* and *pia mater* ; the entire surface is moistened with serous vapour; and frequently there is a considerable quantity of serous fluid. No adhesions have been hitherto observed in this rupture. The condition of the displaced brain is similar to that within the skull, but surrounded at its base with a groove. A part of the ventricle, expanded with water, may be contained in the rupture. Not unfrequently is cerebral rupture accompanied with *spina bifida*.

[(1) Otto observes (*f*) on this point, that it (*Watery Rupture of the Brain ; Hirnwasserbruch*, Germ. ; *Hydrocephalocèle,* Fr.) " seems to depend rather on a diseased partial enlargement of the brain, which, if not in all, certainly in the greater number of instances, depends on *hydrocephalus*, rather than on deficient development of the skull-bones, which seems only to be consequent on that condition." (p. 409.) And " although in some cases, perhaps, a simple hypertrophy of the brain may cause cerebral rupture, yet *hydrocephalus* is usually its cause; therefore almost all the well-observed cases of cerebral rupture have distinctly shown this; and I have also noticed it in the cases which I have observed. In Penada's case (*g*) much water constantly trickled from the cerebral rupture; and in Earle's case (*h*) the water again collected after having been drawn off. Baron (*i*) has related an instance of a female child who was born with a remarkably large head, which at the end of a month measured twenty-nine inches in circumference. " The circumference did not further enlarge, but a swelling began on the top of the head, over the posterior fontanelle, which, in the space of

(*i*) History of a case of Rupture of the Brain, and its Membranes, arising from the accumulation of fluid in a case of Hydrocephalus Internus; in Med.-Chir. Trans., vol. viii. p. 51.

another week acquired the magnitude of a goose's egg. At this period of the disease the mother, on going one morning to take up the child, was very much surprised to find that the swelling had become much smaller, and perfectly soft. She observed likewise a constant dribbling of water from the urinary passages, and that the bed was soaked with the discharge. It continued incessantly for three days and three nights. By this time the swelling had entirely disappeared, the head was considerably smaller, and the integuments which before were very much distended, now fell in large wrinkles over the child's forehead, so as actually to cover the eyes." (pp. 51, 2.) After two months the discharge by the urinary organs diminished, the head acquired greater size than before, " having on this occasion extended itself over the whole of the head and face. * * * A watery discharge, tinged with blood, was seen to ooze from the nostrils and mouth. It continued without ceasing for three days, when the swelling on the top of the head had vanished, and the head itself was much smaller. The fluid never again accumulated in the sack on the outside of the head, nor did the head ever gain its former magnitude, because the discharge from the nostrils was kept up, with slight intermission, till the time of its death," (p. 52, 3,) which occurred about eleven months after. Baron observes in explanation, that " the expansion of the brain, its membranes, and of the *cranium*, seems to have gone on till the parts would stretch no longer, when the rupture took place which caused the first swelling and established a free and large communication between it and the interior of the brain." (p. 55.)

In very rare cases the fluid is contained between the brain and its membranes, and protruding, the latter forms its only contents as in Textor's (*a*) and Thompson's (*b*) cases.

Sometimes a portion of the *cerebrum*, sometimes a part of the *cerebellum* is contained in these ruptures, and an instance is given in which the whole *cerebellum* was found in a rupture through the occipital bone (*c*). There is also usually fluid, on which account the disease has been named *hydroencephalocèle*.

Congenital cerebral rupture is considered by Meckel (*d*) to arise either from collection of fluid in the brain, or on its surface, in which case a portion of the brain and its membranes are protruded. And as to its more frequent occurrence on the occipital bone than elsewhere, Otto says, that this happens because " the occipital bone consists of several pieces of bone, which only at a more advanced period unite, and that the water collected in the posterior horn of the ventricle can act more powerfully upon the four pits formed by the *dura mater* in the occipital bone than upon the other parts, which rather form an inclined plane." (p. 412.) And he says, that in this case " the brain penetrates through the enlarged occipital hole, and the cleft upper *vertebræ* of the neck, or through special holes in the shell of the occipital bone, or at its upper angle." (p. 410.) Among the more rare positions of this rupture must be mentioned the cases mentioned by Moreau (*e*) and Richter (*f*) in which the swelling appeared at the root of the nose and still more rarely where it protrudes into the orbit, the nostril, and the sphenoidal sinus.

These swellings sometimes are much larger than the head itself, of which a case has been recently mentioned by Forgemol (*g*); in this instance the circumference of the head above the ears was only 26 centimètres, whilst that of the tumour was 30 centimètres.

Congenital cerebral rupture sometimes appears to be double, either in consequence of the little yielding of the falciform process of the *dura mater*, and of the longitudinal sinus; or by a tendinous band dividing it into two halves, as in Wepfer's case (*h*), which lived till six years old. These, however, must not be confounded with the actual duplicity of the hernial tumour, "twice noticed" by Otto " at its commencement in one case, and perfectly formed in the other, where the one was again divided into two halves. And in Billard's case (*i*) the scar above the hernial rupture appeared to have been a second rupture."

The cure of these ruptures has been denied, but Otto cites two instances, Billard's, just noticed, and one of Meckel's (*j*), in which it occurred; " scarred spots being

found where in the *fœtus* the water had escaped, and the brain seemed to have fallen together." (p. 412.)]

1262. In *Accidental Cerebral Rupture*, the brain protrudes gradually, by means of its alternating pressure, at the spot where a previous injury of the skull has formed an opening, which is only closed by a cellulo-fibrous substance. As the scar has not the extensibility of the coverings in congenital rupture, so accidental rupture never acquires its size. The swelling always pulsates, increases somewhat during expiration, and lessens somewhat during inspiration. If the swelling can be returned, the edge of the opening in the bone may be felt.

[" The acquired cerebral rupture is," says BECK, " so rarely observed that nothing decided can be mentioned as to its progress. If the case mentioned by LIPSIUS be considered as *hernia cerebri acquisita*, it may be concluded from it, in reference to other cases, that the danger of this condition depends on the disposition of the brain to ulcerative destruction, formation of abscess, and secondary fungus." (p. 176.)

This, truly, is not saying much, and indeed CHELIUS's observations are not more to the purpose. I do not know of any instance where, after the filling up of the opening in the skull which has been consequent on the loss of bone, either by the violence itself which has broken it, by the surgical operation which has removed it to relieve the brain from pressure, or by exfoliation, the result of direct injury or constitutional disease locally affecting the skull bone, the protusion of the brain with its cellulo-fibrous covering has taken place. Indeed, when from either of these causes an aperture has been formed in the skull, and the corresponding wound of the soft parts around it has scarred by its edges inosculating, if the term may be permitted, with the exposed *dura mater*, of which the surface first granulating, either itself becomes converted into a thin skin, or is covered with skin shooting from the surrounding scalp; in such cases, instead of any protrusion of the brain and its covering membranes, there is a seeming depression, which, however, is really only correspondent to the thickness of the bone lost, and not an actual dropping into the cavity of the skull of the cellulo-fibrous substance, which fills up the hole left by the deficient bone. The edge of the bony aperture in these cases is almost invariably thin, scaly, and sharp, as if there had been an unsuccessful attempt to convert the cellulo-fibrous substance into bone. The pulsations of the brain are, when the patient is unexcited, sometimes, though not always, distinctly perceptible through this substance for some little time after the scarring has been perfected; but sometimes, even whilst the *dura mater* is granulating, little or no beating of the brain is observable. As, however, the scar becomes older and tougher the pulsation becomes less and less perceptible, and at last entirely ceases. But though such is the case under ordinary circumstances, yet if, from any cause, the patient be agitated and the circulation quickened, the throbbing of the brain against the cellulo-fibrous scar is distinctly visible, and subsides only as the agitation passes off. This I have frequently observed, as every one must, who has seen large apertures in the skull, from whatever cause resulting, scarred over.

The cellulo-fibrous scar has a very smooth and highly polished surface, at first of a reddish colour, but subsequently as white or whiter than the surrounding skin; and more or less small blood-vessels are seen meandering upon it, which often remain after the general vascularity of the scar has diminished, and it has become white. Like all other newly-formed parts, its vitality is not great, and consequently, it not unfrequently ulcerates superficially, heals up slowly, and again and again ulcerates and heals up in like manner. Although tough and resisting, it is not sufficiently stout to protect that part of the brain it covers from pressure; and therefore, if the fingers be applied on it sufficiently firmly, the brain being pressed, its functions are disturbed, and convulsions, with the other ordinary symptoms of compression, are produced. On the other hand, a sudden and large impulse of blood may so increase the bulk of the brain as to drive it against the cellulo-fibrous scar with sufficient force to burst through it. A very remarkable instance of this kind is mentioned by JAMIESON (*a*) in a girl of thirteen years, who, having fallen from the roof of a house, " broke and shattered her *cranium* at the place where the sagittal and coronal sutures meet, making a depression of the bone of about four inches in diameter ;" for which she was trepanned, and " the depressed pieces of bone being all found separated from the neighbour-

(*a*) The Brain forced, by coughing, through the cicatrice of a wound of the head, &c.; in Medical Essays and Observations, published by a Society in Edinburgh, vol. ii. p. 217.

ing sound bone, were all brought away, and so left a terrible chasm in the *cranium.*" (p. 217.) In three months the integuments were cicatrized, but she continued to wear a plate of lead which had been applied over all the dressings on the fifth day after the accident, for five months; "but then, thinking herself secure, she laid it aside, and continued well seven months more, when the kink-cough, (whooping cough,) then epidemic in the place, seized her, and was so violent one night when she was in bed, that the *cicatrix* in her head was lacerated, and the brain was pushed out at the teguments. Being instantly called for, I found above two ounces of the brain lying on the scalp." (p. 218.) Entire paralysis of the limbs ensued, but she had still the use of her reason and tongue; was much inclined to sleep, had a low depressed pulse, *anxietas cordis*, and involuntary discharge of urine. After continuing in this state for five days, she died; but unfortunately no examination of her body was permitted.— J. F. S.]

1263. Accidental cerebral rupture is distinguished from the so-called fungus of the *dura mater*, by its origin; further, by its usually only occurring in more advanced age, and is preceded by pain, stupor, and the like.

The congenital cerebral rupture may be distinguished from the *blood-swellings* of new-born infants, especially by the latter, in general, being seated on the sides of the head, and being unaccompanied with any symptoms of disturbed cerebral functions; whilst congenital cerebral rupture always arises on the region of the suture. Both *cerebrum* and *cerebellum* may be protruded (*a*), and the greater part of the brain contained in the swelling (*b*).

Trew (*c*), Le Dran (*d*), and others, have described cases of cerebral rupture occupying the right parietal bone, but they are the less to be relied on, as in neither case was there any anatomical examination. The occurrence, however, of cerebral rupture in other parts than the sutures, is proved by anatomical examination (*e*).

Cerebral rupture is distinguished from *watery cysts* on the head of newly-born children, with which it agrees in reference to its seat, and by pressure on it causing cerebral symptoms, by its pulsation and great firmness; the *diagnosis*, however, is difficult when, as frequently, a collection of water occurs with cerebral rupture (*f*).

1264. The *treatment* of congenital and accidental cerebral rupture, consists in returning and retaining the swelling within the skull, for which purpose a sufficient degree of compression is employed by bandages dipped in astringent fluids, or by apparatus of leather, or less suitably, of metal, to such extent, as not to produce any symptoms. Small congenital cerebral ruptures may thus be radically cured, which is not to be expected with those arising from accident (*g*). If the cerebral rupture be large, and the reduction impossible, the swelling must be supported and protected from external pressure. In such cases the puncture of the swelling has been proposed in order to discharge the fluid and lessen the bulk of the swelling. This practice is always very dangerous, although it has been practised with success. The puncture should be made with a fine needle or lancet, and after emptying, the aperture is to be closed to prevent the entrance of air.

(*g*) Sallneuve, above cited. — Martini; in Froriep's Notizen, vol. xi. p. 222.

Punctures have been made very frequently with successful result (*a*) (1).

Tying the swelling (Schneider) (*b*), and incision with the view of extirpation, under incorrect *diagnosis* (Lallemand) (*c*), and the removal of part of the protruded brain (Stanley) (*d*) (2), have had fatal results. Opening the swelling has sometimes first discovered the incorrectness of the *diagnosis*, and a dry dressing, with slight pressure, has been employed till the brain has returned, and complete scarring of the hole in the skull (*e*) has taken place.

[(1) Henry Earle mentions (*f*) the case of a female child born with a transparent globular tumour at the back of the head, which in eight days had increased to the size of a billiard-ball; it "appeared to be in its nature similar to the disease termed *spina bifida*, and to consist of an expansion of *dura mater*, containing *serum*, in consequence of a deficiency of bony or other support at this part." He made three punctures with a common needle, and let out three drachms of fluid. The punctures had not healed two days after, and pressure again discharged the same quantity of fluid. Two days after, the punctures had healed, and the sac was again full; it was then pricked with a very fine trocar-made needle and *canula*, and an ounce of *serum* drawn off. Five times after, at intervals of from to two four days the puncture was repeated, and at the last little fluid was evacuated, and the sac, having collapsed, thickened. For sixteen days the case went on well, but then the sac inflamed, patches of skin came away, and a thin *ichor* discharged from the whole surface. Three days after, the tumour was as large as ever, but opaque and very vascular; it was then punctured with a lancet, and half an ounce only of fluid discharged. Twice afterwards, the tumour was again emptied with the lancet; but two days after the last puncture, the surface of the swelling inflamed, and on the day following, the flap of the last opening began to ulcerate, and in two days more extended down to the cavity of the sac by a small aperture, through which the *serum* continued to ooze. Three days after she died, without any symptoms of inflammation or effusion on the brain. Adams mentions a case which was punctured seven times, the skin gradually thickened, the secretion of fluid diminished, but protrusion, probably a small portion of the *cerebellum*, remained. The child recovered.

Puncture is not, however, free from danger. Corvinus mentions a case (*g*) in which the large swelling was opened by Fried, and death ensued. Seiler (*h*) performed this operation, and the child died comatose on the third day. Von Graefe (*i*) punctured with a trochar and *canula*, and left in the latter to allow the escape of the fluid; but the swelling becoming painful, and assuming a dusky colour, it was withdrawn, convulsions ensued, and the child died.

Pitschaft (*k*) relates two cases of suppurating protrusions in children, in which some of the brain oozed out, and which were cured by the application twice a day of linen spread with honey, with large compresses dipped in decoction of oak bark; and the internal exhibition of acorn coffee and cooling diet. The children's intellect was uninjured.

(2) Stanley's cases are improperly introduced here; they were all fungous growths of the brain, soon after the removal of portions of the skull which had been depressed. Two of the boys died and one lived.—J. F. S.]

C.—Of Prolapses.

1265. A *Prolapse* (*Prolapsus*, *Procidentia*, Lat.; *Vorfall*, Germ.; *Chute*, Fr.) is the partial or complete protrusion of an organ out of its cavity, so that it comes into immediate contact with the external air; in which consists the difference between prolapse and rupture.

(*a*) Froriep's Notizen, vol. xxxvi. p. 346.—Compare Gazette Médicale, vol. iv. p. 299.

Besides the works on Diseases of Women by E. v. **Siebold**, **Jörg**, and others.

1268. *Prolapse of the Womb* designates that displacement of the womb in which it descends more deeply into the *vagina.* According to its greater or less considerable descent, is it called *complete or incomplete prolapse.* It may also be accompanied with *inversion of the womb.*

[" The descent of the womb," says **Sabatier**, " has three different stages, to which have been given the names *relaxation, descent,* and *fall* or *precipitation.* When it is only in its first, or even in its second stage, the womb descends more or less in the *vagina;* a pear-shaped tumour is felt, around which it is easy to carry the point of the finger, and which is pierced at its extremity by a transverse aperture. This tumour is situated higher in relaxation, and lower in descent of the womb. When, on the contrary, the disease has arrived at its third and last stage, the womb is precipitated completely out. It carries with it then the *vagina,* doubled upon itself, and a part of the bladder which is very adherent. Many even of the floating bowels of the lower belly sometimes sink into the kind of *cul-de-sac* formed by the *vagina,* and render the tumour monstrously large." (p. 362.)

To the same effect are **Blundell**'s observations. " There are three varieties," says he, " of this complaint, relaxation, *prolapsus,* and *procidentia.* When the womb protrudes beyond the *os externum*, the disease is called *procidentia* ; when it remains at the outlet, *prolapsus* ; when it scarcely subsides below the brim, it then constitutes what is denominated *relaxation*." (p. 33.) It will be readily perceived that BLUNDELL's *procidentia* is our Author's Complete Prolapse, and that his *prolapsus* and relaxation are included under Incomplete Prolapse.]

1269. In *Incomplete Prolapse of the Womb*, (*Prolapsus Uteri incompletus*,) that organ descends more or less into the *vagina*, and forms a pear-shaped swelling, which protruding only whilst the patient stands, can, on examination, be swept round by the finger, and at its lower part a transverse cleft, the mouth of the womb, is felt (1). Or the womb, with its neck, descends between the external generative organs, in which case the *vagina* is at the same time inverted, and descends with it (2).

The symptoms presented by incomplete prolapse are, dull but constant pain in the rump, loins, and flanks, a weight and pressure in the *vagina*, frequent need of going to stool, often violent urgency, and difficulty in discharging the urine (3). All these symptoms increase if the patient standing long, have exerted herself; and diminish or disappear entirely if she continue for a long time in the horizontal posture. If the neck of the womb have descended between the external generative parts, the movements of the body are hindered, and all great exertion rendered impossible. The irritation which under these circumstances affects the womb, and the other organs of the pelvic cavity, may be participated in by the bowels; and the functions of the alimentary canal are often disturbed (4). At the time of menstruation all these inconveniences increase; it becomes irregular; considerable flooding frequently occurs, and is accompanied with a copious discharge of the whites.

[(1) "Of the descents of the *uterus*, the most common, perhaps the most obscure and the most troublesome, is," says BLUNDELL, "that variety in which the *uterus* descends but a little way, an inch or two into the *pelvis*, technically called *relaxation of the uterus*." The symptoms attending this condition, he observes. often lead the woman, if married, to suppose herself pregnant. If the medical attendant have any doubt of the case, "that doubt is to be set at rest by making a careful examination. If the disease exist, you will observe the upper part of the *vagina* to be very relaxed, and the womb to protrude: and were you to introduce a catheter, you would find there is a tendency to an obstruction and distortion of the *urethra*." (pp. 39, 40.)

(2) The more advanced form of incomplete prolapse BLUNDELL speaks of as "a more frequent disease than *procidentia*, (complete prolapse,) and therefore still more important to be known; in which the womb comes down to the external parts, but not beyond them, and called *prolapsus uteri*." The symptoms, he observes, "are worse at night, because the womb comes down in the evening, the patient having been about all day ;" this observation may indeed be also applied to relaxation. "On the whole, I should say," he continues, "that there are few diseases which are better characterized than *prolapsus uteri*" by its symptoms. If examinations be thought necessary, they "are better made in the evening than in the morning, for in the morning the womb is almost always in its place, whereas, *in the evening*, it is considerably descended, so that the displacement is easily recognised. To this character may be added, first, the laxity of the *vagina*, which, in its upper half, is much more capacious, so that, perhaps you might put a pullett's egg into it there, though the lower part of it may be tenser; secondly, a bearing on the *rectum*, producing irritation; and, thirdly, if you introduce a catheter into the bladder, you will find the passage more or less distorted, the instrument moving about, and perhaps turning round completely by being thrown out of the ordinary line." (p. 37-9.)

(3) The disposition to frequent voidance of the urine may arise either simply from the irritation produced by the displaced womb pressing against the neck of the bladder, or from the pressure preventing the complete emptying of that organ, or from the womb dragging it down and bending the *urethra* upon itself backwards and downwards to a greater or less extent. Upon this point RAMSBOTHAM observes :—"The more vehement the woman's efforts to accomplish the relief of the bladder, the more perfect does the obstruction appear. Nor is this difficult of explanation; because, under these forcible

endeavours, the diaphragm and abdominal muscles both being called into strong action, propel the *uterus* even lower; and in this manner the pressure before existing is increased." (p. 530.)

(4) The irritation of the *rectum* is in either of the two stages now under consideration merely attributable to the pressure of the womb, and not to any dragging.

1270. In *Complete Prolapse, or Falling out of the Womb, (Prolapsus Uteri completus,)* the organ projects entirely out of the external parts of generation; the *vagina* is thereby drawn after it and doubled; the organs connected with the womb are entirely dragged out of their place; the intestines sink into the sac produced by the inversion of the *vagina*, and therefore a void is always noticed in the lower part of the belly (1). All the symptoms mentioned in in complete prolapse here exist in a greater degree; voidance of the urine is specially attended with considerable difficulty, and often entirely prevented (2); qualmishness, sickness, spasm in the belly, sometimes fainting, severe febrile symptoms often occur, especially when the prolapse has taken place suddenly. The swelling formed by prolapsed womb has an oblong, nearly cylindrical form (3), terminates below in a narrower part, on which is found a transverse opening, (the mouth of the womb,) from whence during menstruation blood flows, and into which a probe may be introduced not more deeply than two inches (4). The base of the swelling is attached to the inner skin of the *labia*, by which the introduction of the fingers, near the swelling, is prevented. The tumour has at first a reddish colour, and is sensible: but by contact with the air, friction, and the moisture of the urine, and so on, it becomes inflamed; a copious secretion of mucus takes place on its surface, and it becomes gradually insensible, and overspread with a thick skin, like other parts (5). The inflammation may be severe, and run on to ulceration, and even to mortification (*a*).

(1) In reference to the size of the prolapsed womb and *vagina* and the contents of the sac formed by the latter, Blundell observes:—"I have seen several cases in which the *vagina* has been forming a large tumour lying forth between the limbs; this cyst containing not merely the womb, but in part the bladder, the small intestines, the ovaries, and perhaps the *rectum*; for where you have *procidentia*, it very rarely happens that the womb only descends, generally the other *viscera* come with it, in a larger or smaller mass. A case of this kind, if you are incompetent, you may mistake for *polypus, inversio uteri*, not to mention a large descent of the bladder only; but when you examine the tumour with care, you will frequently discover, first, that on the surface of the tumour, the *rugæ* of the *vagina* are more or less conspicuous; secondly, that you can introduce a catheter into the tumour, provided the bladder be come down; thirdly, that on passing a finger into the *rectum*, it may perhaps descend into the back of the cyst; lastly and above all, that at the lower part of the cyst, the *os uteri* may be found. Sometimes the *os uteri* is so conspicuous that you can see it at the first glance; but at other times it appears under the form of a very minute aperture, the usual tubercle being wanting." (pp. 33, 4.)

Cruveilhier says he has seen one case of prolapse in the living subject in which the bowels descended into the inverted *vagina*, but has never met with it after death. He also observes that in consequence of the peritoneal doubling or pouch between the *vagina* and bladder being much shallower than that between the *vagina* and *rectum*, the *vagina* may be completely inverted in front, whilst it is scarcely ever so behind; and that, consequently, the vertical extent of the swelling is greater before than behind. [This observation seems to me the very contrary of what might be expected.—J. F. S.] For the same reason, he says also, that the front pouch is too slight generally to receive intestines into it, whilst the hind one may receive a large quantity, and that under such circumstances the prolapse may become as large as a man's head (*b*). (This does not appear to me a more satisfactory statement than the former, for did the hinder pouch still remain, the protruded swelling would have the form of a double sac, separated by

(*b*) Livr. xxvi. p. 3.

a cleft, the front one formed by the womb itself, and the hind one by the peritoneal sac containing intestines, and thus in fact becoming a vaginal rupture. But this is not the case, at least in the few cases I have seen (as they generally fall to the lot of the man-midwife, rather than the Surgeon); for in them the prolapsed part was smooth and regular, the whole circumference of the *vagina* having been included in the protrusion, and thus forming a common funnel into which the bowels descend.—J. F. S.

"Many months, or even years, may elapse," says Clarke, "whilst the *uterus* is making this descent; for when the *uterus* has descended so far that it can rest upon the *perinæum*, there it not unfrequently remains, resting upon it as upon a shelf, the violence of the symptoms abating, the parts which suspend the *uterus* above, although much lengthened, being no longer put upon the stretch. From this circumstance it should appear that the greater number of the inconveniences attending this complaint depend less upon the pressure of the *uterus* in the *vagina*, than upon the dragging of the parts above." (p. 68.)

(2) Although difficulty in voiding the urine and frequently even retention are consequent on prolapse of the womb, yet Cruveilhier has given (*a*) instances in which incontinence has ensued. And in the case above mentioned, in which the *rectum* was displaced, he states that there was involuntary discharge of the stools.

(3) Clarke says that "after some time the breadth of the tumour increases, so that it becomes of a globular form." (p. 71.) And further that "the *vagina*, when dragged down by the *uterus*, sometimes undergoes such a degree of distension that its diameter will be greater than that of the *pelvis* itself. In the case of Watkins, who died in Kensington workhouse, the tumour measured more than fifteen inches in circumference, and its length was six inches and a half." (p. 125.)

(4) Cruveilhier confirms Blundell's observation in reference to the altered form of the mouth of the womb, its front lip being sometimes effaced whilst the hind one is very prominent. Its direction also is sometimes changed, the long axis of its aperture being from before backwards, instead of from side to side; and occasionally it is so small as to seem scarcely large enough to permit the escape of the menstrual fluid (*b*).

Cruveilhier states (*c*) that he has invariably observed in prolapse of the womb an elongation of that organ, accompanied with great contraction and narrowing, which occurs principally at the junction of the body with the neck. Cloquet also gives (*d*) an instance of the same kind. Cruveilhier further notices (*e*) that sometimes this elongation and at other times the descent of the womb is greatest. In some instances he found the lengthening so great that when seen within the *pelvis*, the womb appeared to occupy its proper position; and under these circumstances he considers that the disease commenced with the inversion of the *vagina*. "The lengthening of the womb," he observes, "can only be effected by previous softening, in consequence of which the organ becomes in some degree ductile; this softening may be perhaps, purely and simply the result of the slight pull upon the womb" (*f*).

(5) Ramsbotham observes:—"It is worthy of remark, however, that although the local inconvenience is much more distressing when the womb protrudes without the *labia* than when it is still retained within the *pelvis*, yet the system in the former case does not suffer so much; and the reason is obvious. While the vaginal membrane is protected from the external air, its secretion is kept up, and sometimes in an extensive degree; but when exposed to the atmospheric influence it ceases to secrete, and a proportionate quantity of power is therefore saved." (p. 531.)

"It seldom happens," remarks Clarke, "that the *vagina* remains long exposed to the action of the air without ulceration taking place upon its surface. This ulceration does not attack the whole of the exposed surface at once; small spots or patches inflame and ulcerate, and these sometimes run into each other, but the whole surface is seldom covered by them. The ulcerations are generally not deep, and they have the appearance of healthy sores, which readily heal upon the replacement of the prolapsed parts. Whenever ulcerations are met with, the *os uteri* seldom escapes being attacked by one of them." (p. 83.)

Sometimes it happens after displacement of the bladder consequent on prolapse of the womb, that stones form either in the *fundus*, of which Cloquet mentions (*g*) two instances, and Cruveilhier, one; but the latter pathologist has found a stone in that part of the bladder which had not been dragged down (*h*).

Although the *rectum* is less likely to be pulled from its place than the bladder,

yet this has also happened. Cruveilhier relates (*a*) an instance in which the *rectum*, dilated and filled with stool, was drawn forwards a little above its extremity, and formed a funnel-like lengthening. And Cloquet figures (*b*) a case in which, with great enlargement of the *rectum*, a considerable finger-like process descended into the cavity of the inverted *vagina*.]

1271. The *Causes* of prolapse of the womb are predisposing and occasional. The former consist in relaxation of the natural attachments of the womb by copious, long-continued flow of *mucus*, by frequent deliveries, specially if they be very quick, or difficult, and require artificial aid (1). The occasional causes are severe exertion, by which the abdominal muscles are violently contracted, raising heavy weights, violent pressure in going to stool, long-continued standing, and so on. They cause the prolapse the sooner they operate after delivery; and therefore the disease occurs most commonly in women of the lower classes who have often borne children (2). In those who have not borne children it is but rarely observed, and then severe violence must always operate, or the attachments of the womb be relaxed by great previous flow of *mucus* (3). During pregnancy the womb cannot easily protrude, and a considerable prolapse is itself removed by the ascent of the womb. Cases are mentioned (*c*) in which prolapse has occurred during pregnancy, and even during delivery (4); in such, violent straining must have operated, and the diameter of the *pelvis* have been of great size. Any diseased change of the womb which increases its weight, for instance, polyps and so on, or swellings which press upon it, may favour its prolapse (5).

[(1) Among the causes of prolapse of the womb, Blundell notices especially, a large *pelvis*; and he observes, that "this descent of the *uterus*, to which all females may be subjected, when the parts are relaxed, occurs certainly most frequently where the *pelvis* is capacious, and not only in the *earlier* but sometimes in the *later* periods of gestation." (p. 116.)

(2) Ramsbotham observes, that "in the higher circles, indeed, these (last) causes do not obtain; and in them, therefore, we more often find it consequent on miscarriage or accompanying a broken state of health. All women are aware of the necessity of confinement after delivery of a mature *fœtus*, and consequently, if they have it in their power, they willingly follow the course prescribed for them. But when they have passed an *ovum* of only two or three months' age, as they have suffered but little pain and less discharge, and as they had scarcely been sensible of any enlargement in their person before the miscarriage commenced, they consider the occurrence of little import; they think confinement to the horizontal posture for two or three days quite sufficient, and feel a longer restraint irksome, and in spite of advice and remonstrances will busy themselves about their domestic affairs, while still the *uterus* is much too bulky and heavy to be sustained by its natural supporters." (p. 530.)

He also states that "a violent fit of coughing occurring soon after labour or abortion, or an attack of sneezing, although the woman may still retain the recumbent posture, is likely to produce *prolapsus*; and it may be occasioned by a rupture of the back part of the *vagina* and *perinæum*." (p. 530.)

(3) A remarkable instance of prolapse of the womb in a young woman (a virgin) was under Elliotson's care in St. Thomas's Hospital, in 1828 (*d*). She stated that "whilst lifting a person out of a coach, she suddenly felt intense pain in her back, and the *uterus* descended and protruded beyond the *os externum*; its descent was accompanied by profuse hæmorrhage. She was immediately placed in bed and a Surgeon sent for, who replaced the womb. In a month afterwards, feeling herself quite well, she married, and ever since (five months) that period has suffered exceedingly from pain in her back, and from repeated descents of the *uterus*, accompanied with hæmorrhage." (pp. 733, 34).

(*d*) Lancet, 1827-28, vol. ii.

Samuel Cooper states (*a*) that he has seen two instances of prolapsed womb in maidens, in the course of seven or eight years. Ramsbotham has known it twice in unmarried girls about twenty years of age. And other cases are related by Mauriceau, Saviard, Monro, and Cruveilhier.

(4) Ullsamer (*b*) mentions, that he had observed "prolapse of the womb to be in one village, as it were, endemic, in almost all the women who had borne one or two children; and when its cause was subsequently ascertained, it was found that the midwife of the place, who had never been instructed, put all the women, as soon as they had the slightest labour pain, into the labour-chair, which was her only mode of assistance, and let them go on and strain, till either the birth were effected or the woman could go on no longer." (p. 561.) This cause of prolapse is not likely to occur in this country, our women being put in the recumbent posture instead of on the labour-chair; but the fact is worth observation.

(5) Degeneration, accompanied with increased size of the neighbouring organs within he belly may, although rarely, cause prolapse of the womb, as dropsy, or hardening of he ovaries, of which an interesting example is mentioned by Kuhn (*c*).

Clarke observes that "*procidentia uteri* and separation between the bones of the *pelvis* may exist together in the same patient," and mentions an instance of a young lady who, after her second confinement, was thus affected. "During and after this labour there was a considerable discharge of blood, but in other respects she was well. At the end of a fortnight she found herself incapable of standing, and all the symptoms returned, as after her former labour," (pain in the back and groins, uneasiness in the region of the stomach, and impaired digestion, *hysteria*, and mucous discharge from the *vagina*, which were diminished by the use of a pessary, astringent injections, sea bathing, and tonic medicines.) By the use of the means above mentioned, the fresh water bath being used of necessity instead of the sea bath, the symptoms all left her, excepting the pain in the back, and the incapability of standing for half a minute unless supported on each side. Whenever she made the attempt to stand, she placed her hands upon the sides of her hips. This led the author to make a firm pressure there with his own hands; and as long as this was firmly applied the patient could stand, but as soon as this support was withdrawn she was in danger of falling." (p. 78-80.) She was cured by wearing for sometime a leathern belt, an inch and a half wide, applied tightly as she could bear it without pain. Clarke states that he has met with many similar cases, which recovered, but that the "progress of such cases towards health is always exceedingly slow."]

1272. The *prognosis* of prolapse of the womb depends on its degree and causes; it is, however, always doubtful in reference to a radical cure. The symptoms may be very dangerous, especially if the prolapse have occurred quickly.

1273. The *treatment* consists in the *return* of the prolapsed womb, and in the *prevention of its reprolapse*.

1274. In *incomplete* prolapse the return is unaccompanied with difficulty; the womb usually returns of itself, when the patient is in the recumbent posture. But if this do not take place, the womb, after emptying the bladder and *rectum*, must be pushed back with the fingers, which are to be placed upon it, in the axis of the *pelvis*. In *complete* prolapse the reduction is generally more difficult, especially in fat persons, and may be impossible if the womb be considerably swollen and inflamed (1). In these cases the attempts at replacement must be made in the horizontal position, with the rump raised; warm bathing, bleeding, relaxing applications, and the use of cooling remedies, having been previously resorted to; and the reduction must always be carefully made, so as not to increase the symptoms. If the womb prolapse during pregnancy, it must be returned as quickly as possible (2.) If this cannot be done without efforts which may be dangerous to mother and child, it is to be feared that in the increasing size of the womb its circulation may be so prevented as to cause gangrene; in which

case nothing remains but to diminish the size of the womb by breaking the membranes, and drawing off the waters; or the womb remains lying in front of the external genitals till the completion of the delivery, which in many instances (which happens also in those prolapses occurring during delivery) is effected merely by the natural powers, in some by artificial assistance, and even by cutting into the mouth of the womb (*a*). After delivery the bulk of the womb diminishes, and the reduction is easy.

[(1) "**Ruysch** forbids the reduction of the prolapsed womb when it is ulcerated; but," observes **Sabatier**, "as this complication is only accidental, as it is only caused by the continual rubbing to which the tumour is exposed, and by the acridity of the urine with which it is bedewed, no danger is to be feared from this practice. We perceive, on the contrary, that as that which causes and sets up the ulcers with which the *vagina* and womb are affected ceases by its reduction, the ulcers will heal of themselves, when the womb is in its natural place; and experience supports the truth of this reasoning." (p. 365.)

(2) "When prolapse occurs during the course of pregnancy," **Sabatier** says that "its reduction must be attempted, which is sometimes tolerably easy, the pregnancy being but little advanced, if the reduction be made at once, and care have been taken previously to empty the bladder and *rectum* by the catheter and by clysters, and by putting the patient in a proper position. If, on the contrary, pregnancy be far advanced, or if the prolapse have existed some time, the reduction becomes very difficult and in this case it is more prudent to leave the part hanging out rather than to weary the mother and child by unavailing efforts. The womb, however, must not be left to itself; it must be supported by proper bandages, and the patient even kept in bed to the ordinary termination of pregnancy. If the prolapse happen at the time of delivery, reduction becomes useless, and even dangerous. We must then occupy ourselves with the delivery of the child by gradually dilating the womb, which must be carefully supported during the operation, which, though troublesome, presents no greater difficulty than when the womb is in its natural position. The extraction of the *placenta* requires much care. It is easy to perceive this must not be left to nature, and still less that the cord should be pulled in the usual way. The hand being introduced into the womb, the *placenta* must be detached according to **Levret's** method. After which the womb gradually contracts, and the reduction is tolerably easy." (pp. 369, 370.)]

1275. When the prolapse has been returned, the ailment is only of slight extent; and if it have not long existed, the patient requires to be kept several weeks on her back; in passing her motions, she should avoid all straining and sitting up, and she should use local and general strengthening remedies, as volatile frictures of the belly, astringent injections into the *vagina*, strengthening baths, especially tan baths, and so on (1). In this lesser degree of the disease, sponges moistened with astringent remedies may be introduced into the *vagina* (2). In complete prolapse the womb must, after proper reduction, be retained in its place by a mechanical contrivance, the so-called *pessary*.

[(1) **Clarke** says that "in *procidentia uteri*, cold water ought to be applied to the female parts, to the belly, and to the back, by means of a sponge, three or four times a day; and the water for this purpose should be used as soon as it has been drawn from the spring. The water may be rendered still colder by the addition of some matter which is passing from a solid to a fluid state, as ice or salt. Cold water may also be thrown into the *vagina* by means of a syringe, or a piece of ice may be introduced into the *vagina* and suffered to dissolve there. In very slight cases of the disease, when the symptoms are just beginning, and when they are known to proceed from the causes which have been mentioned, they will be removed by attendance to these rules, assisted by the horizontal posture." (p. 95.)

"In *procidentia* of the *uterus*," **Clarke** further observes, "astringent applications to the *vagina* become very serviceable, by diminishing its diameter, and thus rendering it less disposed to receive the displaced *uterus*; and also by restraining the mucous discharge." (p. 98.) "A mixture of alum and sulphate of zinc, in such proportions as the

---

(*a*) Ephémérid. Natur. Curios., déc. II. an iii. p. 375. — **Jalouset**; in Journal de Médecine, vol. lxiii nature of the case may seem to require, will sometimes fulfil the intentions of the practitioner better than either employed alone; and so of all the other mineral astringents which have been in use." p. 101. Of the vegetable astringents, " *cortex quercûs, cortex granati gallæ,* possess a great degree of astringency. They give out their astringent properties to water more readily by boiling than by infusion, and therefore the decoctions of them are to be preferred; they may be used alone, or some of the mineral astringents may be dissolved in them. By these means are procured astringent fluids of such strength, that the *vagina* may be so much contracted as even to render the introduction of the pipe of the female syringe difficult. Astringent injections should be thrown into the parts twice or thrice a day, or oftener, and they should be used cold." (p. 103.)

Upon the subject of injection, **Clarke** states, that " whenever it is found necessary to inject fluids into the *vagina*, and important that they should remain there for any time, the operation should be performed when the woman is in a recumbent position; and if a pillow is previously placed under the hips, in order to raise them a little, the fluid will be less likely to escape. The syringe to be employed should be capable of holding as much fluid as will fill the *vagina*." He objects to the mode in which the holes are generally made in the syringe, by which either the fluid passes out too quickly, or little or none reaches the upper part of the *vagina*, " but if the holes are all placed at the extremity of the pipe, the injection will be thrown to the upper part of the *vagina*, and will be sure of return by the sides." (p. 95–7.)

" When ulceration has attacked the *vagina*, in consequence of exposure to air and pressure," **Clarke** recommends that " a small quantity of some warm ointment be applied to the parts affected by it, such as the following :—℞ *bals. Peruv.* ʒij., *ung. cetacei* ℥j. M." (p. 103.)

(2) **Clarke** objects to the use of sponge, as " the worst material which can be employed for pessaries; it is porous, and will very quickly imbibe the moisture of the parts. The piece of sponge must be large, compared with the size of the *vagina*, or it will be useless; and if it is large, the *vagina* (the dilated state of which was one of the causes of the disease) will be still further dilated; and although whilst the sponge is warm, the *uterus* will rest upon it, and the symptoms may be relieved, yet when it is removed the disease will return in an increased degree." (p. 112.)]

1276. Pessaries, (*Mutterkränze*, Germ.; *Pessaire*, Fr.,) in reference to their form and substance, are very various; they are oval, round, globular, cylindrical, furnished with a stem, and so on; they are made of wood, or cork, caoutchouc, and covered with wax or varnish (*a*).

1277. The oval pessary, made of cork overspread with wax, and provided in the middle with an opening not too large, is the most serviceable. It keeps its place whilst the two ends of the oval thrust against the sides of the *vagina* and *pelvis*. It is to be applied in the following way. The patient, her *rectum* and bladder having been previously emptied, lies on her back, with her rump raised, her thighs apart, and bent towards the belly, the *labia* are to be separated with two fingers of the left hand, and with the right hand the pessary, held flat, is to be thrust so high into the *vagina*, that the mouth of the womb may meet its aperture when it is brought horizontal, and its two ends jut on both sides against the pelvic bones. The patient must remain in the horizontal posture some hours after the introduction of the pessary to ascertain if it still keep its proper place. A larger pessary must be chosen if the womb again prolapse; and a smaller one, if that introduced cause too much presure. At the same time the strengthening remedies, already mentioned, (*par.* 1275,) must be used. If pregnancy occur, the pessary should be removed about the third or fourth month. The patient must then keep herself quiet, avoid all exertion, and, in delivery, all pressure and excitement of labour-pains.

---

[a] **Hunold**, Dissert de Pessaires. Marb., 1779. —**Bernstein**, Systematische Darstellung des chirurgischen Verbandes, p. 352 —**Meissner**, above cited.—**Herrez de Chegoin**; in Mémoires de l'Académie de Médecine, vol. ii. p. 319.—Mad. **Rondet**, Mémoire sur l'emploi des Pessaires de caoutchouc. Paris, 1833.—**Zimmermann**, Erfahrungen und Mittheilungen bewährter Aërzte und Wundaërzte neurer Zeit über Prolapsus und Carcinoma Uteri nebst einer gründlichen Beleuchtung der Pessarien. Leipzig, 1834. fol. No. 148. —Gemeinsame Zeitschrift für die Geburtskinde, vol. vi. pt. i. ii.

[When the prolapse is so great that the globular pessary, which CLARKE thinks is the best, will not be retained, neither can be kept in the *vagina* by any common bandage, he recommends " a pessary to be chosen of the size which the case requires, and a small slip of brass to be attached to it by its two ends, leaving a space between the instrument and the centre of this piece of brass; a belt of leather, long enough to go round the patient's body, is also to be prepared; to the centre of which behind, a brass wire, as thick as a common quill, is to be attached by a screw. This wire is now to be properly bent, and the pessary being introduced into the *vagina*, the wire is to be passed between the pessary and the piece of brass attached to it; and being brought up between the thighs, it is to be attached to the fore part of the circular strap. The reduced parts are by this means supported by a pessary, and this is kept in its place by the unyielding piece of metal." (p. 127.)]

1278. The use of the pessary is frequently accompanied with much inconvenience, as it causes pain, inflammation, stinking discharge, suppuration, and even degeneration of the generative organs; in many cases it cannot be worn, and in many the prolapse cannot be kept up for any time (1). In such cases the only help consists in an *organic narrowing of the vagina* with or without excision of its walls, by means of the *suture*, *Elythroraphy*, (HALL, BÉRARD,) *Colpodesmoraphy*, (BELLINI,) or by junction of the *labia* by means of the *suture*, *Episioraphy*, (FRICKE,) or by the *introduction of a ring* (2).

[(1) The use of pessaries has of late years gone much out of fashion, on account of the many inconveniences which they cause; and in their stead many of our leading accoucheurs prefer the use of a modified T bandage upon the belly and *perinæum*. Among these, Dr. HULL's utero-abdominal supporter is perhaps the most known and commonly used in this country; and I have seen it employed very successfully several times in my own hospital patients, for whom it has been prescribed by our obstetric physicians. It does not appear certain that HULL was the real inventor of this bandage; at least, one very similar to it had been long previously made by SHELDRAKE of Leicester Square, and another and more simple had been invented many years before by KING, a Surgeon at Clifton. I am not aware, however, that any good explanation of the way in which such bandages act had been given, till HULL brought out his apparatus. He considers " *Prolapsus Uteri*, not as a displacement of the womb merely, but as a loss of that perfect equilibrium between the upper and lower portions of the *abdomen* which is essential to the preservation of the relative situations of the *viscera* it contains, and also a dislocation of the *uterus* and bladder; and in some cases, as especially dependent upon a pouch-like relaxation of the whole perinæal region. His method of cure consists in giving the weakened and relaxed portions of the muscular walls of the abdomen adequate mechanical support, which directly replaces the *viscera*, and gives back to the weakened walls their lost tone" (*a*).

The apparatus consists of a broad soft elastic pad, covering the whole hypogastric region, upon the middle of which the front end of a spring, like that of a common truss, acts, and from the hind end a strap passes round the opposite side of the body, and fastens on the pad. " The effect of this pad is to give the weakened lower portion of the abdominal muscles a congenial support, which, at the same time that it diminishes their labour, stimulates them by the well-known power of mechanical pressure upon muscular tissue, to a permanent renewal of their vigour. It reduces the distended *hypogastrium*, aids the upward forces of the belly, and by its direction, upwards and backwards, directly relieves the pelvic *viscera* from the unnatural pressure of the downward forces." That portion of the apparatus above described, is not always " competent to the entire relief of all cases of this species of uterine displacement; the *perinæum* sometimes losing so much of its muscular and organic contractility, as not to resume its natural dimensions and situation, even when the downward forces are stayed by the hypogastric pad. In cases of this character, although the abdominal support of the apparatus does certainly relieve many of the distressing sensations of the patient, yet the distended floor of the *pelvis* remains a *cul-de-sac* for the reception of the *viscera*,

---

(*a*) This extract I have taken from " A brief Account of the application and uses of the Utero-Abdominal Supporter, for relief and cure of *Procidentia* and *Prolapsus Uteri*, patented by A. G. HULL, M.D." London. Published by WEISS, of the Strand, who is agent for these bandages. The original pamphlet, published in America about ten years ago, I have in vain endeavoured to procure.—J. F. S.

whenever that apparatus is removed for a length of time. To obviate this liability, as also to give tone to the *vagina* by the stimulus of mechanical pressure, thereby to diminish its calibre, and restore it to its natural situation, the doctor applies against the *perinæum*, externally, a prism-shaped pad or cushion, made of sponge, firmly encased in cloth, which is held in its place by a strap passing between the thighs, and over the perinæal region, in the manner of a T bandage. This perinæal cushion, with its rising and sinking in perfect accordance with the respiratory motions of the *diaphragm* and abdominal walls, keeps up an equal, firm, and, to the patient, agreeable pressure upwards, is a good substitute for the intervaginal pessaries."

SHELDRAKE's bandage is very similar to HULL's, but without the spring.

KING's bandage is very simple, and I am informed very efficient; it is, in fact, a T bandage, of which the circular part is in two pieces, one passing round the back of the *pelvis* from below, the upper front spine of one hip-bone to the other, and its ends connected in front by an elastic strap, rather wide in the middle, to which is attached a perinæal strap, also elastic, and padded more or less thickly in the *perinæum*, according to circumstances.

(2) PHILLIPS (*a*), in a case of prolapsed womb, for the relief of which the patient could not bear the use of any pessary, attempted to produce a scar of the *vagina* by destroying its mucous surface with caustic, for the purpose of causing such contraction of the passage as would prevent the descent of the womb. Having introduced a three-pronged *speculum vaginæ* and freely expanded it, he liberally applied lunar caustic upon two of the exposed surfaces, and afterwards washed out the *vagina* with warm water. The application gave very little pain, but its effect did not extend beyond the *epithelium*, and when this peeled off there was not any appearance of granulating surface. Six weeks after he "used the fuming nitric acid, brushing it over a larger surface by means of a camel's-hair pencil. The pain it occasioned was greater than that which followed the use of the nitrate of silver, but still it was not severe nor long-continued. The inflammatory action was much more decided, the whole thickness of the mucous tissue sloughed, and a fair granulating surface, yielding a considerable purulent secretion, was established." (p. 495.) The descent of the womb did not at first appear to be much checked, and it was thought of bringing the sides of the *vagina* together with suture, to which however the patient would not assent. Gradually the descent of the womb diminished, and for eight months had entirely ceased, the capacity of the *vagina* having diminished to that of a woman who had never borne children.

If pessaries be used, they should be occasionally removed to cleanse them of any acrid or gritty substance which may have become attached and be likely to excite inflammation and ulceration. CLARKE also remarks, that "instances too have occurred, where parts of the instrument have been destroyed by a spontaneous change taking place in it, and angular portions of it having been left, which have produced similar bad effects;" of which he gives an instance. And he also mentions a remarkable case, in which "a supposed schirrous tumour surrounding the *os uteri* was found to be a cork pessary, introduced many years before, and rendered very rough by calculous matter deposited on its surface. It was withdrawn, and all the symptoms subsided in the course of a week." (pp. 116, 17.)]

1279. According to HALL (*b*), after the womb has been forced down by the patient's efforts as much as possible, two parallel cuts should be made along the whole length of the *vagina*, from the neck of the womb to its entrance, through the mucous membrane, which is to be separated, so that an interspace of two and a half inches is laid bare between the two incisions. A stitch is then to be put in through both edges of the wound near the neck of the womb, the womb itself to be returned, and the threads tied firmly together. Several ligatures may in the same way be gradually applied (1).

IRELAND (*c*) has successfully practised HALL's method, which he has only modified with the view of avoiding more certainly the bladder and *rectum*, by making the incisions on the sides nearly parallel, but converging at their extremities, by removing the flaps above and below, and applying all the sutures before returning the womb.

(*b*) London Medical Gazette, vol. ix. p. 269. 1830.

(*c*) Dublin Journal, vol. vi. p. 486. 1835.

Velpeau and **Berard** have performed **Ireland's** modified operation, but they also removed a third slip from the front of the *vagina* (*a*).

[It has been a dispute with whom this operation originated. **Velpeau**, in his Clinical Lecture just cited, says, that "the first idea of this operation is due to **Gérardin**, who described it in a memoir which he presented to the Société de Médecine de Metz ou de Nancy, which however was never published. He proposed to contract the *vagina*, and if necessary even to obliterate it, in women in whom the *catamenia* had ceased. He found many opponents to his ideas, which were rejected." (p. 276.) **Velpeau** does not mention in what manner it was proposed to effect the contraction of the *vagina*, neither does **Gérardin** himself in his letter to the Académie (*b*), in which he says, that "before 1823 he had proved that the pessary might be replaced by and the cure of prolapsed womb radically effected by a surgical operation." It is therefore just possible, though not very probable, that **Marshall Hall** might have been aware of **Gérardin's** suggestion before he proposed and had his operation performed by **Hemming** (*c*) in the autumn of 1831.—J. F. S.

(1) **Dieffenbach** (*d*) made use of the actual cautery for the cure of prolapsed womb; but not being satisfied with it, has laid it aside. **Lawrie** of Glasgow, however, mentions (*e*) the case of a girl of eighteen, who had prolapsed womb suddenly produced by carrying a heavy tub; nitrate of silver was freely applied, astringent injections and other remedies used, and strips of the mucous membrane dissected off the sides and back of the *vagina*, but without benefit. He then, having dilated with **Weiss's** *speculum*, applied the actual cautery on either side of the *vagina*, nearly as high as the womb. The operation was very painful, the external parts became œdematous, she had retention of urine, some pain in the belly, and hysterical symptoms, which readily yielded to mild treatment. She was kept in the recumbent posture for six weeks; and left the hospital nine weeks after the operation, without the least tendency to the renewal of prolapse; but having a circular contraction of the *vagina*, just below the womb. Nine months after, the protrusion recurred, after long standing and unwonted exercise. The actual cautery was again applied, the same symptoms produced, but subsided, after one bleeding, aperients, fomentations, &c. She was kept in bed for nine months; then allowed to get up, wearing a compress in the *perinæum*, and a T bandage, and was perfectly cured.

Ker (*f*) mentions a case of prolapsed womb, which would not yield to the usual means for its return, but was treated effectually with ergot of rye. The woman had had external prolapse for three years, which returned when she lay down; but at last a complete prolapse of the *uterus* took place, which could not be returned. "Sixteen hours after, the *uterus* was considerably enlarged, little, if at all, below the size of the fœtal head; indeed, in a condition decidedly œdematous." Attempts at reduction, mild aperients, warm fomentations and injection, all failed; and after having been persisted in for twenty-four hours, it was determined to give the *Secale cornutum* in scruple doses every three hours. After taking the first dose she complained of a great deal of grasping grinding pain in that which was down, very much resembling labour, and these pains increased on each succeeding dose. On examination, a material diminution in the size of the prolapsed womb was found to have occurred, so much so that the *rugæ* of the *vagina* were perfectly manifest, and without any great effort the reduction was effected.]

1280. **Bellini** (*g*), with a pair of hook forceps, grasps the upper segment of the externally-protruded *vagina*, draws it down, and, giving the forceps to an assistant, begins at the outer edge of the vaginal commissure, upon the left side of the swelling, with a flat curved needle armed with two threads, to unround it, and with the thread form a half-circle, in the form of a horse-shoe, or an ∩, and thrusting the thread in and out at intervals of two lines. To prevent injury to the *rectum*, the forefinger of the left hand must be introduced, for the careful direction of the needle, which should be passed no deeper than the walls of the *vagina*, and with every stitch only one line of it is to be taken hold of. When the upper part of the swelling is reached, it must be surrounded with

four stitches, and the needle carried in the same way downwards, to complete the horse-shoe. The ends of the threads are now to be drawn together, so as to fold up the prolapse, and then fastened with a loop knot. The after-treatment consists in rest, blood-letting, cold fomentation, and diet. After two or three days, the threads may be drawn tighter. A portion of the mucous membrane of the *vagina* separates after ten days, a scar forms in the *vagina*, and prolapse never recurs.

1281. *Episioraphy* is performed, according to **Fricke** (*a*), in the following manner:—After the patient has been properly placed, the Surgeon takes hold of one *labium* with one hand, thrusts in a pointed bistoury about two fingers from the upper commissure, and a full finger's breadth from the edge of the *labium*, and carries it down to the *frænulum*, where he brings it out again in a small curve, so that a portion of the *labium* of a finger's breadth width is separated, and then the upper still attached part of this portion of skin is to be completely cut through in an oblique direction. The same proceeding is to be adopted with the other side, and so carried on to the *frænulum* that a part of the latter is removed, and both cuts brought together at an angle, at a finger's breadth from the *frænulum*. After the bleeding from the spouting arteries has been stopped by torsion, and from the little vessels by cold water, both edges of the wound are to be brought together with from ten to twelve stitches. It should be previously considered whether the prolapse can be kept up merely by quiet position or not; and in the latter case, previous to putting in the stitches, a piece of oiled sponge, upon which a thread is attached, should be introduced into the *vagina*. The patient, after the operation, is to be laid on her side, with the rump somewhat raised, and the knees tied together. Applications of cold water or lead wash should be made to the wound, and the urine drawn off by the catheter, for the first few days. Though, however, no perfect union ensue, yet usually the prolapse is partially kept up. The vaginal *mucus* and the menstrual blood escape, and *coitus* can be effected by the opening remaining at the upper part. Should pregnancy ensue, the adhesion may be divided, or cuts on the sides made at the time of delivery (1).

(1) **Kock** (*b*) uses the quill-stitch in *episioraphy*.

Plath (*c*) gives the account of a birth after *episioraphy*. A bridge still existed; in delivery the lower opening dilated, and was still further enlarged by three cuts on the sides. The result was completely satisfactory.

[**Geddings** of Maryland (*d*) has performed successfully the operation of *episioraphy* four times in the following manner. The patient being placed in the ordinary position for lithotomy, and the *prolapsus* reduced, one *labium* was put on the stretch by an assistant, and an incision was commenced, with a common scalpel, about a finger's breadth from the upper commissure, and the same distance from the edge of the *labium*. The incision was carried downwards with a bold sweep, and terminated by a slight curve inwards, and at a little distance behind the *fourchette*. A slip of the *labium*, of a finger's breadth in thickness, was thus severed from the external parts, taking care not to cut through the mucous membrane of the *vagina*. Making traction on this slip downwards and inwards, the mucous membrane of the lateral portion of the *vagina* was then dissected up to the extent of an inch and a half, and detached with the excised *labium*. The same was repeated on the opposite side, the incision being so directed as to intersect the first cut at an acute angle, and remove the *fourchette* with the other parts. After the slight hæmorrhage had ceased, an oiled sponge was introduced into the *vagina*, and the two raw surfaces brought into apposition by the quilled suture of

five stitches. A compress of lint, and a T bandage were applied, and the parts kept cool with cold water. The sponge which had been introduced to keep up the womb till adhesion had taken place, was generally removed about the fifth or sixth day; and the sutures were taken out, as the parts seemed to have united.]

1282. For the purpose of holding the *labia* together, and thereby preventing prolapse, a hinge ring, about the size of a large earring, should be used; it is to be drawn through the lower part of both *labia* and closed, so that it may lie in the region of the *frænulum* (*a*).

1283. An old prolapse oftentimes cannot be returned without causing anxiety, pain in the belly, costiveness, and other symptoms (*b*). In this case, the womb must be supported with a bandage, and care must be taken for the proper emptying of the bladder and *rectum* (1). If the completely prolapsed womb be so changed by disease, as for example, by *schirrus*, that its removal is indicated, this must be effected by the ligature (2) or by incision; the latter at least has been done successfully, by Langenbeck (*c*) (3).

[(1) When, in consequence of the altered position of the bladder often attending prolapse of the womb, the urine cannot be voided, and it becomes necessary to introduce a catheter, the altered direction of the *urethra* must not be forgotten; and according to the directions of Cruveilhier, the instrument must be directed downwards and backwards with its concavity downwards. and thus it "first enters the displaced part of the bladder and is afterwards raised by a lever-like movement into that portion of it still remaining in its natural situation" (*d*).

(2) The removal of a prolapsed schirrous womb was effected with the ligature by Recamier and Marjolin; but the woman died from some cause independent of the operation. Cruvelhier, who mentions this case (*e*), objects to the treatment as being accompanied with great risk of including a portion of the bladder in the ligature. He recommends, in preference, cutting through the back of the *vagina*, into the doubling of *peritoneum* between it and the *rectum*, then drawing the womb through the aperture an detaching it from its cellular connexions with the bladder.

(3) In Langenbeck's operation, the womb, after cutting across the *vagina*, was drawn down, separated from the *peritoneum* without opening its cavity, and cut off, excepting a small portion of its *fundus*, which being healthy, was left undisturbed.]

II.—OF PROLAPSE OF THE WOMB WITH INVERSION.

Crosse, John Green, An Essay, literary and practical, on Inversio Uteri; in Trans. of the Prov. Med. and Surg. Assoc., New Series, vol. i. p. 285. 1845. 8vo.

1284. Under the term *Prolapse of the Womb with Inversion* is understood the dropping down of the *fundus* of the womb into its cavity, and the sinking down of the *fundus* and body into the mouth of the womb, into the *vagina*, and even its protrusion at the external generative parts.

(*a*) Kraus; in Medicinischen Correspondenz blatt des Würtemb. ärztl. Vereines., July, 1843, Nov. 20.—Heyfelder, Das chirurg. und Augenkranken Clinicum der Univers. Erlangen, 1843, p. 45.

(*d*) Livr. xxvi. p. 2.

(*e*) Livr. xvi. p. 4.

It is, therefore, distinguished as *incomplete* and *complete inversion;* in the former case the *fundus* of the womb protrudes more or less through its mouth, and forms a semicircular swelling, which is encompassed by the mouth of the womb; in the latter the whole womb is protruded, from its *fundus* to its neck, through its mouth, and lies in front of the external generative parts in shape of a pear-formed swelling.

[CROSSE observes:—"Inversion of the *uterus* is either partial or total; the latter can exist only in one degree, and admits of no subdivisions. Partial inversion, on the contrary, comprises very many degrees; and there are both physiological and practical reasons for noticing and describing three, by way of classification; namely, *depression, introversion,* and *perversion.*

Depression, the first division and slightest degree of partial inversion, is present when any portion of the entire thickness of the walls of the *uterus* becomes convex towards its cavity or interior, without going to the extent of being invaginated, or brought within the grasp of the rest of the *uterus,* supposing it to contract by the action of its muscular coats. The interior convexity is answered by a concavity of the same extent on the exterior surface of the womb. The posterior, lateral, or even perhaps the anterior part of the body of the organ, may be thus displaced after parturition; but usually the *fundus* is the part affected. * * * The palpable evidence of this degree of inversion is obtained by examination through the *parietes* of the *abdomen,* or by the hand *in utero* meeting with a convexity of more or less firmness according to the atonic or contracted state of the part, and giving the idea of a *placenta* still remaining, after the entire *placenta* has been removed. If the *placenta* be still adherent, its attachment is to the inverted portion, and any attempt to remove it by traction will increase the inversion.

Introversion is when so great a part of the *fundus* is displaced, as that it comes within the grasp of the portion of the *uterus,* into which it is received. The greatest degree of this displacement consists in the *fundus* and continuous part of the body of the *uterus* being received into the remainder of its body and *cervix,* the convexity of the *fundus* being palpable at the *os tincæ.* The inverted portion is in a situation to be resisted, supported, compressed, and otherwise acted upon, by the uninverted, by which it is always surrounded. In proportion to the degree of introversion is the depth and extent of the peritoneal pouch opening towards the *abdomen.* The uterine ligaments are in part drawn into this pouch, and the *ovaria* approximate, the marginal circle corresponding to the angle of inflexion. On examining above the *pubes,* the circular margin of the *uterus* can be felt forming the boundary of the inversion, and the *uterus* and part of the body of the organ are wanting; in a thin patient, and where the abdominal *parietes* are relaxed and yielding, the fingers of the accoucheur may even enter the orifice of the peritoneal pouch, pressing those *parietes* before them. If the *placenta* be still attached, it is felt at the *os tincæ,* or in the cavity of the *uterus,* and judged to be of unusual size; if partially detached it allows of great hæmorrhage, which may cease on its removal, if the inverted *fundus* contract, and be felt firm to the touch; but hæmorrhage continues if the inverted mass be soft, indicating that it is still in a state of *inertia.*

Perversion is when more or less of the inverted portion of the *uterus* projects through the *os tincæ;* in its greatest degree the whole body of the *uterus* as well as the *fundus,* passes inverted through the *os,* the *cervix* only remaining *in situ,* encircling the contiguous or highest part of the inverted portion, all the rest being uncompressed and unsupported by the *uterus.* The peritoneal pouch is lengthened, and the proper uterine cavity nearly obliterated. Where "the inverted part is surrounded by the *cervix,* it may constrict it, producing congestion and even strangulation in all the rest of the inverted organ below. The angle of inflexion (so first named by RADFORD of Manchester) is always below the middle of the body of the *uterus.*

In considering the successive steps of the inverting process, we trace the descent of the *fundus* through the uterine cavity until it projects at the *os,* fills the *vagina,* and reaches the external *labia;* and the process may go on in the same direction to its completion, the inverted *fundus* and even body of the *uterus* prolapsing externally, until the encircling *cervix* descends, under expulsive efforts, to a level with the *labia,* and becomes apparent under ocular examination. But if the *labia* resist sufficiently the further descent of the *fundus,* and part of the body of the *uterus* remains still uninverted, may not the process be carried to its completion by ascent of the *cervix?* No author has hinted at this view of the subject, and yet its correctness must be admitted, in order to explain the well-established fact, that where the inverted *fundus* and body of the *uterus* are still in the *vagina*, the *cervix* is felt high above the *pubes*, even near to the navel, sometimes taking the situation the *fundus* would normally occupy, the *vagina* being proportionately stretched and carried upwards,—changes which can only be explained by supposing that, at a certain stage, the inversion ceased to progress by descent of the *fundus*, and was continued and completed by ascent of the *cervix*. If the *placenta* be still adhering, it precedes the *fundus*, is felt in the *vagina*, or observed at the external *labia*, giving the attendant an impression of its being firmer than usual, and of greater size. * * * If the *placenta* be already away, a convex tumour occupies the *vagina*, of a greater or less size, according to the proportion of the body of the organ inverted, having a soft, slightly nodulated surface, bleeding easily under the touch, its highest part encircled by the *cervix*. If the *cervix* only remain uninverted, the *fundus* and body of the *uterus* may be so large as to fill the bony *pelvis*, distend the *vagina* and render it difficult, if not impracticable for the accoucheur to reach the *cervix;* but as often as the inverted mass prolapses at the *vulva*, the encircling *cervix* can be felt. * * * Examination above the *pubes* may enable the accoucheur to detect the orifice leading to the peritoneal pouch, formed by the inverted *fundus* and body of the *uterus*, or in the case of external prolapse at the *vulva*, to convince himself of the absence of the organ from the abdomen. (p. 283–99.)

"In all degrees of inversion," says Crosse, "there is a concavity or pouch lined with *peritoneum*, and open toward the general peritoneal cavity. In simple depression the intestines rest in the concavity; and as the pouch or *cul-de-sac* increases, the intestines may, if the opening into it be large, occupy this pouch, so that in total inversion, with prolapse, they may actually descend beyond the external *labia*, still resting in the peritoneal bag, which the inversion has occasioned." (p. 308.)]

1285. The inversion of the womb occurs either suddenly or gradually; the former is possible only during delivery, when it quickly follows if the woman be in the upright posture, and strain very violently at the moment when the child is forced out; or it may occur from pulling at the navel-string, from too short or coiled up navel-string, and so much the more as the *pelvis* is wide (1). The inversion may be produced gradually by polypous growths at the *fundus* of the womb (2), by a slight in bending of the *fundus*, which remains after previous delivery, and gradually increases; in which case there is generally only imperfect inversion (3).

(1) According to Hachmann (*a*), there may be spontaneous inversion dependent on spasm, probably from deficient contraction of the womb, analogous to partial contraction, which is observed in stricture of the womb, in which case, for instance, the relaxed and toneless *fundus*, sinks inwards, is grasped by the contracting body, and descends completely down to the mouth of the womb.

[(2) On this point Clarke observes:—"It is said that inversion may be produced by the weight of a *polypus* attached to the *fundus* of the *uterus*. This cause may, of course, render unmarried women the subjects of this disease; but it will be rarely met with, first, because *polypus* itself is infrequent; secondly, because the *polypus* must be very large and heavy, that it may, have the power of drawing down the *uterus*; thirdly, because an unimpregnated *uterus* is unyielding and firm; and fourthly, because the *polypus*, to produce that effect, must be attached to the *fundus* of the *uterus*." (p. 150.)

Crosse, however, says:—"Next to pregnancy, the most frequent cause of enlargement of the *uterus* is a polypous tumour, which, when attached, as often happens, to the internal *fundus* of the organ, may occasion its inversion in all the different degrees that have been referred to. Any of the various tumours that progress towards the uterine cavity, and take the polypoid form, may induce inversion; but the vesicular *polypus*, being softer and of less density than others, and having usually a narrow neck, is less likely, in the progress of its growth and of its expulsion, to cause uterine inversion, whilst the *polypus* of great density, and with a broad basis, and particularly the fibrous, is not unfrequently followed in its later stages by the displacement in question." (p. 321.) Inversion of the womb from *polypus* is as various as from any other cause. "At first so partial," says Crosse, "that the *polypus* is still situated in the *uterus*, and next it descends into the *vagina*, bringing the inverted *fundus* to the *os;* then the *polypus* protrudes at the *labia*, the displacement being carried to the greatest degree of partial inversion, and filling the *vagina*, whilst the *cervix* alone continues

---

(*a*) Einige Falle von krankhafter Lageveränderung des Uterus; in Hamb. Magazin der Ausländ Literatur. Nov., Dec., 1834, p. 352.

in situ, or is itself inverted, with part of the *vagina*. A further stage remains, in which the uterine inversion is total, and prolapses externally, bringing with it the *vagina*, also inverted. (p. 331.) If the *polypus* be attached to any part of the *fundus*, at the terminating opening of either of the Fallopian tubes, or in the interspace between those openings, it may determine a partial and limited inversion, whilst still remaining wholly or chiefly within the *uterus*. The symptoms are the same as a *polypus* produces, without inversion, and cannot be considered characteristic, although generally more severe, such as uneasiness in the uterine region, forcing pains, *leucorrhœa*, and *menorrhagia*." (p. 324.)

(3) "In addition to what has been already stated, we may," says Crosse, "enumerate coagulated blood accumulated in the *uterus*, and an hydatidous growth, or mole. occupying its cavity, each of which has been known to cause uterine inversion." (p. 338.) Of the majority of the cases referred to the former cause, Crosse has considerable doubt. "Some," he says, "are unsatisfactory, others evidently stated in error, the epoch of the inversion having manifested itself to the unsuspecting or uninstructed observer, (perhaps some seven or ten days after delivery,) not being the commencement of the displacement, which was coincident with the termination of the labour. With more correctness may we regard distension of the *uterus* from blood as a cause of the *relapse* of inversion." (p. 339.) As to the cases uncomplicated with pregnancy, "where blood was the primary cause of enlargement of the uterine cavity," he says, "I cannot quote any so objectionable as the case related by Mr. Watkinson (*a*), in which a woman of fifty years of age had inversion take place under protracted and very severe *menorrhagia*, in which, as Watkinson supposed, in a relaxed state of the *os uteri*, and perhaps of the *uterus* itself, owing to protracted hæmorrhage, the organ became inverted on the expulsion of *coagula*. At the expiration of four or five years the inverted womb hung half way down towards the knees, with a neck formed by the inverted *vagina*, about the size of one's wrist. The patient was reduced to imminent danger of life by sloughing and abscess, when the *uterus* was removed by incision below a ligature placed on the *vagina* with a fatal result. Of inversion following the expulsion of hydatidous masses, he mentions the case recited by Dr. Thatcher, of Edinburgh, in his lectures, in which the woman acknowledged that she had pulled away a protruding mass, which consisted of an immense accumulation of hydatids, firmly cemented by nearly cartilaginous bands, and had thus produced the same result as from injudiciously pulling the umbilical cord for the extraction of the *placenta* after delivery. There was "every diagnostic mark of the inverted *uterus*, with the *os uteri* clear and defined, surrounding its upper base." Attempts to return it were fruitless, and "at midnight the *uterus* was close down on the *os externum*. Next morning it was found fully protruded at the *vulva*, in shape and size like the largest caoutchouc bottle for injection." It could not be returned, and therefore, on the third day "a ligature of silver wire was applied close to the *os uteri*, with the double *canula* as for *polypus*. The ordinary means for supporting strength and preserving cleanliness were used. On the third day from the application of the ligature separation was nearly effected, and the slightly remanent portion was divided with the scalpel." (p. 340–42.)]

1286. The quick-formed inversion of the womb is commonly accompanied with severe pain, bleeding, inflammation, and swelling of the prolapsed part, and if it be complete, with sickness, fainting (1), convulsions, depressed powers, small and scarcely distinguishable pulse, and with danger of mortification and death; in a complete inversion, however, all the symptoms may be absent (Hachmann.) The slowly forming inversion of the womb prevents the discharge of the urine and stools, causes irregular menstruation, bleeding, inflammation of the womb and neighbouring parts, pain in the belly, hæmorrhoidal inconveniences, whites, hardening, excoriation and ulcers of the womb (2), bad nourishment, dropsical swellings, hectic fever, and so on.

[(1) Upon these symptoms Dailliez (*b*) makes the following interesting observation:—"A loop of intestine may follow the *fundus* of the womb, insinuate itself into the cavity, of which the entrance is at first very large, become strangulated, as has been observed after bursting of the womb, and give rise to new symptoms, which have

---

(*a*) London Medical and Physical Journal, vol. vii p. 435. (*b*) Thèse.

hitherto been merely regarded as sympathetic. The intestinal pains, the swelling of the belly, the sickness, vomitings, hiccough, so frequently attributed to reversion of the womb, may actually depend in some women only on this strangulation." (p. 80.)

(2) "Whilst the inverted *uterus* remains in the *vagina*, the discharge (excepting at the periods of menstruation) will be of a mucous kind," observes **Clarke**; "but if the *uterus* falls lower, so as to protrude beyond the external parts, the exposure of that surface, which, in a natural state, lined the cavity, to air, as well as to occasional injuries, may induce inflammation and ulceration over a part, or the whole of its surface; and the mucous discharge may be changed to one of a purulent kind, so considerable in quantity as to debilitate the constitution, and to cause all the common symptoms of weakness. If there are any ulcerations upon the surface of the upper part of the tumour, formed by the inversion of the *vagina*, they will be circumscribed, and rarely cover its whole surface." (p. 155.)]

1287. Inversion is distinguished from prolapse of the womb by the pear-shaped swelling, broad below, on which no opening is found (*par.* 1269.) The distinction from a polyp of the womb is always difficult, and depends on the following circumstances; in the complete inversion, the form of the swelling resembles indeed that of the polyp, but it is enclosed at the upper part by a fold, and neither the finger nor a probe can be passed up between the swelling and this fold, as it can in polyp; the completely inverted womb has also at its upper part, from being hollow, a soft and yielding character. But this distinction is especially difficult in an incomplete and slowly produced inversion. When the inverted womb still lies in the *vagina*, it is broader above than below, but the polyp has the directly contrary form; the swelling of the prolapsed womb has a more definite feel than the polyp, which last is more movable and its surface smoother than that of the prolapsed womb. The simple inbending of the womb may in some degree be felt through the skin of the belly. The *diagnosis* is considerably assisted by the origin of the ailment after previous delivery. But all these circumstances may, in certain cases, lead to no definite results; for the form of polyps as well as their sensibility and mobility varies; both swellings may present a smooth or uneven surface; the polyp may appear soon after birth; the examination of the belly in stout persons gives no result. It seems to deserve particular attention that the polyp, when it has once penetrated the mouth of the womb, grows remarkably quick.

1288. The first indication, in inverted womb, is to return it to its place as soon as possible, because otherwise by the quickly ensuing inflammation and swelling, its replacement is difficult and impossible. If the inversion be incomplete and recent, it is sufficient to thrust up the bottom of the womb gently through its mouth, with the fingers of the right or left hand collected in a conical form. If the inversion be complete, if it have continued some hours or days, the *fundus* must be grasped with the whole hand, and whilst gently compressed, should be pushed up in the axis of the *pelvis*. In difficult cases the object may perhaps be attained, if two fingers be passed by the side of the protruded *fundus* of the womb into its mouth, enlarging it and then first returning that part next the mouth and afterwards the bottom of the womb. After the reduction is completed, the hand is to be kept in the womb till, by simultaneous rubbing and sprinkling the belly with cold water, it have perfectly contracted, and the after-birth if still retained, have been thrown off (1). Quiet in the supine posture with the rump raised, and the avoidance of all exertion, are favourable to keeping the returned womb in place (2). If the replacement be impossible, from the inflammation and swelling, or if on account of the increase of dangerous symptoms, especially of convulsions, it cannot be undertaken, then, after the womb has been gently thrust into the *vagina*, it must be attempted to diminish the swelling by suitable antiphlogistic treatment, and by simultaneous emptying of the bladder and *rectum*, before proceeding to its return (3). Attempts at replacement must not be continued too long, nor too violently, because thereby the most dangerous symptoms arise; but should be repeated after a suitable pause. In one such case the womb has been seen to return by the ensuing contraction (*a*).

(1) If the *placenta* remain still attached to the prolapsed womb, its separation must be first effected, before any attempt at replacement, because the reduction together with that of the *placenta* is considered impossible; but as this is contradicted by experience, the removal of the *placenta* renders the reduction doubtful, and dangerous bleeding may be easily produced; so the greater number of modern accoucheurs agree to attempt its reduction, together with that of the *placenta*, and only to remove it when it adheres very slightly.

(2) In chronic inversion, it becomes more difficult to preserve the womb in its place, because it has lost its power of contractility. To effect this, some have recommended the introduction of pessaries, (ROUSSET,) of several pieces of sponge, (JÖRG,) of a caoutchouc bottle, (FRIES,) and of peculiar supports for the womb, (LÖEFFLER, SIEBOLD.)

["In a case where the *uterus* has been long inverted, and lies in the *vagina*, (the latter cavity having undergone no change, except from distension,) it will not be advisable," says CLARKE, "to recommend any other remedy than the injection of some very mild astringent fluid three or four times a day, into the *vagina*. Some restraint will thus be placed upon the quantity of the discharge, and the parts will be kept clean by it. Pessaries are useless; the *vagina* being already so completely filled that nothing more can be retained in it." (p. 156.)

(3) In the treatment of recent inversion, CLARKE lays down, that "the *uterus* is to be first returned to its usual state and natural situation; and the case then becoming simply one of a retained *placenta*, is to be treated as such; but if, neglecting this order of proceeding, the *placenta* should be first removed, a number of bleeding vessels will be exposed before the *uterus* can contract, so as to restrain the hæmorrhage; and the chance is, that the patient may die from its effects." (p. 152.)

Inversion of the womb "is occasionally met with in the chronic state," says CLARKE, attended by a mucous discharge. The symptoms of the chronic state resemble those of *procidentia uteri*; and, an examination being made, a tumour is found either in the *vagina* or hanging out of the external parts. Such a tumour may be mistaken for *polypus*; but in the latter disease, the *os uteri* encircles the tumour; in inversion of the *uterus*, the *os uteri* forms a part of the tumour itself. Moreover, the inverted *uterus* is sensible; *polypi* of the *uterus*, on the contrary, are void of feeling." (p. 153.)]

1289. If the return of an inverted womb be impossible, dangerous symptoms must be prevented by properly emptying the bladder and *rectum*, by the avoidance of all effort and so on, and by the introduction of a pessary to prevent, if possible, the further descent of the womb. But if the inversion be accompanied with threatening symptoms, if the replacement be in nowise possible, if the womb be in a state of cancerous or other kind of degeneration, then may the cases related (*b*) of successful removal of the womb, determine us to its removal with the knife, after previously applying a ligature; or with the ligature, in which it is best to apply two

C., Case of Loss of the Uterus and its appendages soon after delivery; with remarks on the propriety of removing that organ in cases of Inversion or Scirrhus. London, 1836 ligatures with a single needle and to tie them on each side to prevent slipping; it must, however, be borne in mind that the intestines may have descended in the place of the inverted womb.

[When the inverted womb falls out of the body, drawing with it the *vagina*, and increasing weakness is produced by the quantity of the discharge, "if this case is left to itself, the woman," observes CLARKE, "either drags on a miserable existence for a number of years, or her life is cut short by the constant drain. Cases of this kind can receive very little benefit from external applications; and it is obvious that not much is to be expected from internal medicines. Powdered chalk or *lapis calaminaris*, sprinkled upon the part, may check the discharge a little; the oxide of zinc may in some measure abate its quantity; but it will not remove it altogether; and the same observation will apply to astringent applications generally. The following application may have a beneficial effect:—℞ *liq. calcis* ℥iv., *mucil. sem. cydon.* ℥vj. M. * * * It may be considered more prudent, if the discharge diminishes in consequence of such applications, to persevere with them, rather than to risk any danger which may arise from an operation. In those cases of inversion of the *uterus*, where the woman has passed the menstruating age, where her comfort is destroyed by the disease, and where the profuseness of the discharge threatens her with death from the debility which it produces, it may be advisable to recommend the performance of an operation, which has been in many instances attended with success, and from which the author has known a patient recover after she has attained the age of sixty; this operation is the removal of the inverted *uterus* itself. Although it is not expedient to subject a patient labouring under a chronic inversion of the *uterus* during the menstruating portion of her life, under ordinary circumstances, to the danger of the removal of the organ, the system of a woman may be so drained by the excessive discharge as to warrant the performance of the operation." (pp. 157, 58.)

It does not appear that the removal of the inverted womb by ligature is dangerous; the cases treated by CLARKE himself, as well as those he quotes, did well; so also BLUNDELL's case, and he observes:—"Indeed, I have not heard even of any cases in which the operation has been followed by fatal consequences; though such cases must, I presume, occasionally occur." (p. 145.) In one of CLARKE's cases, "a strong silken ligature was used, and although nearly three weeks elapsed before the *uterus* was separated, during which symptoms of inflammatory action presented themselves in full force, with vomiting and *diarrhœa*, the result was most successful, and perfect health was restored. (p. 159.) In another, in which the operation was performed by CHEVALIER, "a ligature was applied round the contracted part of the tumour, that is, where the *uterus* terminated, and the *vagina* began. It was tightened daily, until about the eleventh or twelfth day, when the parts included in the ligature were absorbed, and the *uterus* fell off. During this time the patient complained of very little pain." (p. 163.) BLUNDELL "applied the ligature with HUNTER's needle, as in the case of *polypus*, and in eleven days the *uterus* came away; it sloughed, and softened down, so as not to separate bodily, in the form of *uterus*, and the recovery of the patient was complete." (p. 144.) In Dr. JOSEPH CLARKE's case (*a*), "the pressure by ligature, which the partially inverted *uterus* bore for many days, not only with impunity, but with decided benefit to the future health, constitutes the leading feature of this case. When the *uterus* became completely inverted, its amputation became an easy operation, and the patient's previous good health suffered no diminution." (p. 161.)

Dr. SYMONDS of Oxford (*b*) applied a ligature in a case of inverted womb in a young woman, eighteen years of age, two years and a half after the delivery of a living child. The *placenta* had been long retained, and was brought away with great violence. The ligature was tightened every other day, and the patient did not suffer much pain till this had been several times repeated. The tumour separated on the fifteenth day; three or four days after, dangerous symptoms appeared; and on the sixth day after, she died. On *examination*, about a quart of pus was found in the *peritoneal* cavity; the bladder and *omentum* were adherent; and there was a free and open passage between the *vagina* and the abdominal cavity, of a circular form, capable of admitting the finger, and consisting of the ring of the *os uteri*, and about three lines of the *cervix*, close upon it were the ovaries, of natural appearance, and the remains of the Fallopian tubes.

Meisner, above cited, p. 212.

Clarke, Charles, above cited, part i. p. 142.

1290. When the canal of skin which forms the *vagina* protrudes wholly or entirely from the *labia*, it is called *Prolapse of the Vagina.* It may consist either of the internal membrane alone, or of all the membranes of this canal; in the former case only is it possible for the womb not to descend at the same time. The prolapse is either *complete* or *incomplete;* in the former, the whole of the *vagina* descends; in the latter, only a part at one or other side, and usually on the front.

[The prolapse which **Chelius** treats of more especially, must be considered as the *anterior prolapse* of the *vagina*, and differs decidedly from the form described by **Clarke**, who says, "the term *procidentia vaginæ* is here meant to imply a relaxation of the posterior part of the *vagina*, so that this part is lower than the natural defined edge of the *perinæum*." (p. 142.) From this description, it may be fairly distinguished as the *posterior prolapse* of the *vagina*.

John Burns (*a*) says, that "the *rectum*, in every degree, is more or less drawn down, and brought forward, sometimes so much so as to form a kind of pouch in the protruded *vagina*." (p. 78.)]

1291. The *Complete Prolapse* is at first characterized by a soft bluish red, slightly wrinkled or smooth ring which, by its gradual lengthening, acquires a cylindrical form, and, at its lower end, has an aperture into which the finger may be introduced, and the mouth of the womb felt. The prolapse is increased by standing, and generally returns in the horizontal posture. If it have existed for some time, the condition of the skin is changed, it becomes dry, and similar to the common tegument; it may inflame, pass on to ulceration, and so on. Inconveniences are connected with prolapse of the *vagina* similar to those accompanying prolapse of the womb, only in a slighter degree; the patient feels, especially if the prolapse have occurred suddenly, a pressure in the *vagina*, a constant disposition to void the urine and stools; she is subject to a copious flow of whites, the menstruation becomes irregular, and on every violent exertion prolapse of the womb is to be feared. *Imperfect Prolapse* forms a blind sac, at the under end of which there is not any opening, and at the side of which the finger may be passed into the canal of the *vagina*.

The prolapse which depends on vaginal rupture, has been already mentioned (*par.* 1248.) The *diagnosis* between prolapse of the *vagina* and that of the womb is easily determined by the symptoms mentioned, by the excrescences in the *vagina*, and by examination.

["Very few symptoms attend this complaint," says **Clarke**; "some pain in the back is present, but this is not considerable; some transparent *mucus* comes away from the *vagina*, and the woman complains of a relaxation in the parts, and of something projecting from them." (p. 145.) "In the earlier stage," **Blundell** (*b*) observes, "the tumour is very small, perhaps not larger than the ball of the apex of the forefinger, forming at the back or front of the *vagina*, or laterally, or in all the three positions at

---

(*a*) Principles of Midwifery. Ninth Edition.

(*b*) Above cited.

once, protrusions by no means uncommon. These protrusions, if small in size, may be looked upon as natural to the part; but they often show a disposition to increase, and then begin to attract attention." (p. 29.)]

1292. The following circumstances predispose to prolapse of the *vagina;* relaxation, and slight cohesion of the *vagina*, and its surrounding cellular tissue in cachectic subjects after a violent flow of whites, after frequent deliveries, especially if the *perinæum* be torn, after too frequent *coitus*, onanism, and the like. The occasional causes are, violent exertions in lifting heavy weights, in violent vomiting, shrieking, and the like; violent efforts in delivery, especially in improper postures, in going to stool, and so on; also pressure from the parts surrounding the *vagina*, for instance, from large stones in the urinary bladder, from retention of urine, dropsy of the belly, and so on, may produce prolapse. It arises in general suddenly or slowly.

[CLARKE's form of prolapsed *vagina* is considered by him to arise from the habitual constipation of the bowels, to which women subject themselves, in consequence of which "the lower part of the intestinal canal becomes so distended sometimes as to make the posterior part of the *vagina* approach near to the anterior part of the *pelvis*, and in this way the diameter of the *vagina* may be much diminished. This extreme distension of the gut at length diminishes, or takes off the power of contraction upon its contents, and the strength of the *sphincter* muscle is increased by its frequent resistance to the contraction of the intestines and abdominal muscles; at length, when, by the operation of purgative medicine, or by the natural strong efforts of the intestines, or by manual assistance, (which is sometimes required,) the lower bowel is emptied of its contents, the pouch formed by it, and the posterior part of the *vagina* continues, so as to form *procidentia vaginæ.* If the forefinger of the Surgeon is passed into the *anus*, under such circumstances, and carried forwards, it will be directed into the pouch so formed. This disease appears sometimes to be produced by piles, acting in the same manner as habitual costiveness. * * * The complaint may also be produced by cysts belonging to diseased ovaries, falling down into the hollow between the *rectum* and the posterior part of the *vagina.* In one case where this happened in labour, it was only "terminated by opening the child's head, by means of which operation the life of the woman was saved. After the labour, the cyst went up again into the cavity of the *abdomen*; and the *vagina* being no longer pressed down, regained its natural situation." (pp. 143, 44.) CLARKE further observes, that "when the patient is in the horizontal posture, the tumour made by the prolapsed *vagina* is somewhat smaller than when she is erect; but it never goes away altogether. Its size is sometimes as large as a hen's egg. Very few symptoms attend the complaint." (p. 145.)]

1293. A small and recent prolapse of the *vagina* is easily returned if the patient being put in the horizontal posture, on her back, with the rump raised, the protrusion be pressed back with the finger well oiled, and the skin of the *vagina* also pressed every where on the sides. If the replacement be prevented by inflammation and swelling, or the prolapse be of long standing, luke-warm baths, softening applications, a longer continued supine posture, and attention to the free voidance of the urine and stools must be employed.

[For curing the posterior prolapse, CLARKE says:—"The practitioner is to direct proper means to keep the *rectum* empty, and thus to remove one of its causes; afterwards he is to endeavour to restore the tone of the gut. Without attending to the first of these objects, the second cannot be accomplished; and unless the tone of the bowel is restored, the mere emptying of it will be useless. Purgatives given by the mouth, and clysters thrown into the *rectum*, are the means by which the first of these objects is to be attained. If piles are present, the class of resinous purgatives is to be avoided. * * * As in some instances, the gut is so much distended as entirely to have lost its power of action; neither clysters nor purgatives will be of any avail; the clyster-pipe, as it passes into the *rectum*, will be blocked up by *fæces;* and purgatives will only bring a large quantity of *fæces* down, which will add to the bulk, already too great. Nothing remains in this case but to empty the *rectum* by manual operation. * * * The patient being placed on her left side on a bed, her knees being drawn upwards, the forefinger of the right hand of the Surgeon, covered with oil, is to be introduced into the *vagina;* a marrow-spoon, or the small end of a common table-spoon, covered with oil, and warmed, is then to be introduced into the *rectum;* and by means of it, assisted by the finger in the *vagina*, the *fæces* are to be scooped away. A large clyster is then to be thrown up; and if any fæculent matter should be lying in the sigmoid flexure of the *colon*, it will be brought down into the *rectum*, where it may be easily removed. For the purpose of giving tone to the *rectum*, the same means are to be employed as are calculated to produce similar effects in other parts of the body. Bandages are not applicable to this case. The object is to give support to the posterior part of the *vagina* and to the weakened *rectum*. A globular pessary answers both of these purposes very well, and it should be carefully adapted to the size of the *vagina*. * * * Costiveness in future is to be carefully prevented." (p. 146–48.)]

1294. To prevent the reprolapse of the *vagina*, the introduction of pads filled with astringent substances, and steeped in red wine, or sponges cut in conical form, moistened with astringent fluids, should be used previous to employing the pessary. The patient must for a long time observe rest and a horizontal posture; and employ the remedies advised (*par.* 1275) for strengthening the relaxed parts. In old prolapses, which cannot in any way be kept up, the operation already mentioned in prolapse of the womb, (*par.* 1278,) by narrowing or closing the *vagina*, can alone get rid of the evil.

---

*III.—OF PROLAPSE OF THE BLADDER.

(*Prolapsus Vesicæ*, Lat.; *Harnblasenvorfall*, Germ.; *Chute de la Vessie*, Fr.)

CLARKE C. M., above cited, part i. p. 130.

BLUNDELL JAMES, M.D., above cited, p. 31.

[*Prolapse of the Bladder* may be easily mistaken for prolapse of the *vagina*, and has been confused, though with less cause, with that of the womb, although some of the symptoms are common to both. The prolapsed bladder falls back, just behind its neck, carrying with it, into the cavity of the *vagina*, the front of that passage, and the two together descend less or more completely, and appear at the *os externum* in form of a convex or hemispherical swelling, which fills up the orifice, and sometimes protrudes between the *labia*, the transverse folds of the *vagina* being less or more distinct upon it, according as the bladder is full or empty.

The sensation of bearing down is less great than in prolapsed womb; but it is in some women greatest in the horizontal posture; in the night, therefore, the patient is much annoyed with this sensation, which is frequently accompanied with a perpetual desire to make water. The discomfort and protrusion is greatest when the bladder is full; but it rarely happens that that organ can be completely emptied, the muscular fibres forming the pouch or tumour not appearing to have the power of contracting completely. The peculiar symptom of prolapse of the bladder is a pain referred to the navel, with a sense of tightness there; the pain greatest when the bladder contains the largest quantity of urine, diminishing as the water is voided, and ceasing when the bladder is nearly or entirely emptied. This symptom is especially noted by CLARKE, who thinks it may be accounted for, perhaps, by a stretched state of the umbilical ligament, (the remains of the umbilical arteries,) or by the dragging upon the navel itself. The pressure of the back of the bladder on the front of the *vagina* lengthens the cellular tissue, connecting it with the front of the *cervix* *uteri;* but, as it does not yield readily, it drags down with it the anterior lip of the *os uteri*, and lengthens it very much. Hence, "the *os uteri*," says Clarke, "instead of being found in the centre of the *pelvis*, opens directly backwards, and lies in contact with the posterior part of the *vagina;* so that the space between the elongated anterior lip of the *os uteri*, and the posterior part of the *vagina* is very small;" and sometimes, indeed, the *os* is patulous. There is often a discharge of *mucus* in these cases, and rarely it is profuse.

Prolapse of the bladder is distinguished from prolapsed womb, by the absence of the stomach symptoms, which rarely, if ever, occur when there is mere displacement of the bladder (Clarke.) There is not any aperture in the protruded part, as in prolapsed womb; but the swelling has a regular form, filling up more or less completely the cavity of the *vagina*, but admitting the finger to be passed up between itself and the hind wall of that passage, to the mouth of the womb. Clarke says that, on tracing the tumour in the *vagina* "to its origin, it may be felt lying between the *os pubis* before, and the *uterus* behind; and a practitioner can hardly fail to discover that it is formed by fluid." The latter part of this observation is correct; but its relative condition with regard to the womb will depend upon the extent of the dropping down of the bladder, and the position of the womb is rather above than behind the tumour. The diminution of the size of the swelling when the bladder is emptied, is also another characteristic, and distinguishes the disease from the encysted or other tumours which occasionally, though rarely, form in the neighbourhood of these parts.

If the catheter be introduced, it can be easily felt within the cavity of the swelling, (an excellent indication of the disease,) and, under voluntary urging, the swelling is found to increase considerably in size. By these two marks the disease may be readily known (Blundeel.) If the prolapse occur during labour, care must be taken not to mistake it for the descending portion of the membranes, by which irreparable mischief has been inflicted (Castle.)

The *treatment* consists in keeping the bladder constantly empty, in the injection of astringents, and in wearing a pessary, either globular, or egg-shaped. The latter is, perhaps, the most preferable, "particularly," says Clarke, "where the diameter of the *vagina* is but little increased by relaxation." All exertion which might force the bowels down upon the bladder should be avoided, and the patient should be kept quiet; and, perhaps, if confined to the recumbent posture upon her face, with a catheter in her bladder, so that the urine might pass off without being retained in the bladder, and thus the disposition of that organ to contract encouraged and kept up till the *vagina* had recovered sufficient tone to resist the pressure of the protruding bladder.

The use of the pessary and astringents is said to be generally sufficient for the cure of prolapse of the bladder; but sometimes the instrument cannot be borne, and the downward pressure of the swelling is so great and inconvenient, that the woman is incapable of any exertion, or even of moving about without much distress. Under such circumstances, it will be advisable to take out a portion of the front wall of the *vagina*, and thus diminish its disposition to yield to the pressure of the bladder.

Cases of prolapse of the bladder do not often fall under the Surgeon's care in this country, except when the ordinary treatment with pessaries and injections fail, and it

becomes a question whether the patient can be relieved by an operation. One such instance has come under my care, and been considerably relieved; for, although not entirely cured, the patient has been enabled to resume her ordinary occupation.

Case.—M. A., aged twenty-five years, a fair-haired, hysterical, well-formed, but not stout single woman, came under my care,

Oct. 24, 1837.—She began to menstruate when sixteen years old, and for the first year had good health; but since that period has been continually ailing, and suffered very much at her monthly times. The menstrual discharge has been scanty, and not lasting more than two days, when she has been so unwell as to be quiet; but, when engaged in her occupation as housemaid, and able to be about, it has been plentiful, and lasted four days. She has always had much bearing down, and, within the last three or four years, has suffered much from *leucorrhœa*, and the bearing down has so increased, that, for the last twelvemonth, she has been unable to follow her usual employment, and been compelled to give up her place. Five months ago the protrusion was as large as a cowrie-shell, and, when she exerted herself, it became much larger. She did not usually void her urine for twelve or sixteen hours, and then the protrusion disappeared. Micturition was always accompanied with sharp smarting pain; it was long before she could void any water; sometimes not for eighteen or twenty hours. By repeated efforts, however, she was at last enabled to empty her bladder, and never required the introduction of a catheter. Last spring she attempted wearing an Indian rubber pear-shaped pessary; but it was useless, as, whenever she walked about, it immediately dropped out. For the last three months she has kept in bed, used astringent injections, and worn a sponge pessary, which has kept the swelling up, but without any actual improvement.

Nov. 11.—I made an examination with the view of ascertaining the feasibility of removing some horizontal slips of the front of the *vagina*, as suggested to me by my friend Dr. Locock. As she had not made water for three hours, the bladder was partially filled, and a swelling, about the size of a cowrie, protruded through the *os externum vaginæ*, and just appeared in front of the *furcula*. Some of the *rugæ* of the *vagina* were very distinct, and the swelling began a full inch behind the orifice of the *meatus*, which canal was not at all displaced, and allowed the ready entrance of a catheter into the bladder. Slight pressure returned the tumour, and the *os uteri* was then found depressed to within an inch of the *os externum*. On expanding the *vagina* with the *speculum*, it was seen to be so drawn off from the front of the neck of the womb, that no appearance of neck remained; but from the plane of the *os uteri* to the front wall of the *vagina*, was one continuous and very open curve; but the *cul-de-sac*, behind the neck, was, on the contrary, very deep. Having withdrawn the *speculum*, I could, without difficulty, nip up an inch and a half of the *vagina* from the back of the bladder; and having ascertained this, it was determined to remove a slip or two of the lax part.

Nov. 12.—Having bound her, and put her in a position for lithotomy, as there was but little protrusion, and her efforts failed of driving the swelling down, I commenced the operation by pinching up the front of the *vagina*, and passing a *tenaculum* through, drew it down; I then introduced a needle and ligature, about an inch below the *os uteri*, and half an inch above the *tenaculum*, for the purpose of drawing down the *vagina* after the removal of the proposed slip, and to prevent difficulty from its retraction. The portion of the *vagina* included on the *tenaculum* was then drawn down, and having been felt to be separated from the bladder, I made a horizontal cut, about an inch and a half in length, carefully separated the *vagina* from the bladder, first with the blade, and after with the handle of the knife, till I could hold the slip with my thumb and finger, and withdrew the *tenaculum*. I then separated the flap till it was an inch in depth at the middle, but tapering to a point at each end, and cut it off horizontally below with a pair of scissors. There was pretty free bleeding, but only one small vessel could be found to tie, and it ceased after sponging with cold water for about a quarter of an hour. I then introduced three platina sutures upon very small needles, the middle one first, and having brought the edges of the wound close, twisted them together. She was then put to bed upon her face, a catheter introduced, and the urine directed to be withdrawn hourly. The operation was not difficult, nor very painful; but there was a little awkwardness in getting the sutures through, perhaps from the small size of the needles.

Nov. 13—Last evening there had been a little oozing of blood; but during the night a considerably quantity; one sheet having been soaked through, has been removed, a second is in much the same state, and there is about eight ounces of clot in the hair of the *pubes*. She feels rather faint, but her face is much flushed. She has passed plenty of water, both through and by the side of the catheter; but she complains of much pain in the chest and loins, with great tenderness of the belly.

As it did not seem well to permit the continuance of the bleeding, I removed the catheter, cleared away all the clot, and introduced the *speculum*. No clot was found in the *vagina*, but there was a free oozing from between the lips of the wound. Failing to find any vessel, I removed the right suture, upon which the wound gaped, and seizing its upper lip, whilst she strained, I drew it down, and carefully examined the whole surface, from which the oozing was very free. After considerable trouble, I found and tied three small bleeding vessels, which, however, I believed to be veins, and the bleeding being checked, I passed a silk suture, and again introduced the catheter.

Nov. 15.—She has not had any more bleeding, and the pain and tenderness of the belly have diminished, but the latter still continues about the region of the bladder. There is a little fetid discharge from the *vagina*, and some small thin flakes of adhesive matter in the urine. On examining with the *speculum*, I found all the sutures had begun to ulcerate, and therefore removed them; the metallic ones with some difficulty, as they did not readily untwist. The wound did not gape, but the extent of the union could not be ascertained. On the front of the *vagina*, near the neck of the womb, was a seemingly ulcerated spot, perhaps where the first thread for drawing down had been passed.

She had a tolerably good night, and next morning drew off about half a pint of very ammoniacal urine, with much adhesive flakes; this evacuation was followed with great pain in the bladder and *pudendum*, for about half an hour, and then gradually subsided. In the course of the day, the quantity of water drawn off increased, and became quite clear. She had not any febrile excitement, but still complained of much pain in the left breast, across the pit of the stomach, and over the whole belly, which is probably only hysterical. She had an increase of the throbbing in the wound, which has been constant since the operation.

Nov. 17—The throbbing has diminished, and the discharge from the *vagina* has increased, and is distinctly purulent. She has still much pain in the region of the bladder, and the urine is much loaded with adhesive matter.

Nov. 19.—Is better, and has passed plenty of urine, which yesterday was scanty, and the sediment in it mucoid. Less throbbing in the *vagina*, but the discharge increased. Complained of pain and soreness, with beating in the umbilical region, and some tenderness on pressure, as also about the region of the bladder; and also pain in the upper part of the thigh. Her bowels are kept regular with castor oil. In the course of the evening she became very hysterical, and it was necessary to give her some æther and tincture of henbane, with camphor mixture. But next day she had recovered herself, and her bowels having been freely moved, the abdominal pain almost entirely ceased.

Nov. 22.—The *speculum* was introduced to examine the state of the parts, but being inefficient, was withdrawn, and the *os externum* being held widely apart with the fingers, she was desired to bear down. This brought the wound into view, which had not yet united, but was healing by granulation. There was a free *leucorrhœa*.

Jan. 6, 1838.—Up to the present time, she has been kept in bed, and the wound has healed. The discharge continues very profuse, and she has much pain in the loins. On examination, the bladder was found still falling back, as previous to the operation.

A fortnight after, she was allowed to get up and walk about; the descent of the bladder soon became as at first, and protruding between the *labia* when she exerted herself. The operation had therefore been unavailing. In the middle of *March*, after going about more than usual, the bladder protruded to the size of an egg, and on the following day still more; but a few days rest in the recumbent posture restored the old condition.

As she continued very delicate, it was determined she should go to the sea-side for the improvement of her constitutional powers, and she went to Brighton in *April*, wearing a globular pessary, which kept the bladder up; but after a month, as it caused much pain in the region of the bladder, it was thought advisable to remove it, which was done with much difficulty, and in course of the following week the protrusion returned. For some weeks she used a cold salt water hip-bath daily, and the recumbent posture; and afterwards, sea-bathing three or four times a week, but without diminution of the discharge, and with no benefit to her health.

The *vagina* was then cauterized with the caustic potash thrice, at intervals of a week; from the first application there was little sloughing, the second caused much, and the third less, but more than the first; and during the separation of the sloughs, she used injections of cold sea water continually, and took forty drops of the tincture of muriate of iron twice a day. She left Brighton in *September* without any material improvement, and returned home to her usual employment. Soon after, the dragging pain in her loins and the protrusion increased, and if she walked a short distance, these became worse, and were accompanied with pain in the upper part of both thighs. In *December*, a ring pessary was introduced to relieve the protrusion, but its pressure upon the *rectum* was so great, that she could not pass her motions, and after having been worn three days, it was necessary it should be removed.

She came under my care again in *January*, 1839, much out of health and spirits; nothing therefore was done but to improve these, and I did not make any examination till the middle of *April*. The bladder was then still fallen, but less than before, merely appearing at the *os externum*, and returned with the least pressure with the fingers; the scar on the front of the *vagina*, of which the shortening was very decided, was quite visible, and though not hard was tender; the position of the womb and the state of its lip was nearly the same as at first. Thinking, as little pressure kept the bladder in place, a small oval pessary might be useful, I introduced one; but the next day the bladder had slipped down between it and the *pubes*, and she had so much pain that it was necessary to remove it.

Although kept in the recumbent posture, she still had severe dragging pain in the loins, equally as when she was about; and as she objected to the application of caustic again, but was willing to submit to an operation, I determined on removing a vertical piece of the *vagina*, which was done

May 18.—She was now placed standing with her body bent at right angle with her legs, and resting upon a table, with the *pelvis* rather higher than the shoulders. A pewter *speculum*, slit lengthways and the edges widely opened, was introduced into the *vagina*, with the gap towards its front; a catheter was introduced; the *labia* held apart by assistants, and the *perinæum* pressed up with the *speculum*. I then seized the front of the *vagina* with BEAUMONT's needle and drew it down till I could conveniently pass a *tenaculum* through it, which done, the needle was withdrawn. Pulling up the *vagina* with the *tenaculum* as far as I could, I cautiously made two semi-elliptical cuts about an inch and a half in length, from half an inch below the neck of the womb to about the same distance behind the *urethra*. The right cut was made freely with a common scalpel, but the left required a little more care and was made by short portions, cutting upwards with a *phimosis* knife which was very convenient; and the insulated piece was then dissected off the bladder, leaving a gap about half an inch wide, which was increased to an inch by paring the edges of the wound. There was, as in the former operation, very free oozing of blood, and it became necessary to tie two small arteries. Three sutures were put in very readily with BEAUMONT's needle, and the *speculum* having been withdrawn they were tied and the operation completed. She was put to bed on her face, and an elastic male catheter introduced, so that the urine might escape as soon as it entered the bladder; and twenty drops of laudanum, thrice a day in mint water, were ordered for the purpose of keeping the bowels costive.

May 23.—Excepting a little discomfort from position, she has been tolerably well. There is now a little purulent discharge, and on gently separating the parts one suture was found separated, but there was little inflammation about the wound.

May 26.—She was rather flushed and feverish, and had not passed water for some hours; the catheter was withdrawn, found to be clogged, and when introduced again, a pint of high-coloured urine passed, which greatly relieved her. Another suture and one of the ligatures came away in the evening, and on the following day the remaining suture and ligature.

June 7.—The catheter having caused some irritation to the bladder, was removed, and a common female instrument given her to pass frequently, so as to prevent distension of the bladder. Up to this time the urine has been more or less turbid, with flakes of adhesive matter, as after the first operation.

June 18.—Having now been on her face for thirty-one days, latterly without much inconvenience, she was allowed to lie on her side.

July 22.—An examination was made; there was less protrusion, but the bladder still falls back into the *vagina*. The wound is perfectly healed; but there is tenderness about the neck of the bladder. The discharge continuing, a small bag partially filled with powdered oak bark was introduced into the *vagina*. The bark swelled so much with the moisture that it was necessary to diminish its quantity.

Aug. 5.—The discharge is materially diminished, but the *vagina* slips below the bag.

Aug. 25.—Was allowed to dress herself, but still kept in the recumbent posture. The bark bags were left off, and a saturated solution of alum in elm bark was ordered to be injected frequently during the day.

Sept. 5.—She has not gained much advantage by the injection; the bladder is just visible at the *furcula.*

Sept. 20.—She returned home, being able to walk about much better than previous to the operation, and had but little pain in the loins; the discharge, however, continued. She was directed to wear a pad in the *perinæum,* supporting it with a T bandage, and to use the oak-bark bags.

On the whole I was fearful that she had not derived any material benefit by the operations to which she had been subjected, but was agreeably surprised on seeing her in

November, 1840, to learn that soon after her return home, she had been able to stand whole days at the ironing-table without any protrusion. For some months she has been able to go about without difficulty, and do anything she has to do; but she says there is some protrusion. I examined her, however, and found little or none.

In the following *January* she married, and was confined in the ensuing *December.* She was taken in labour on the 16*th,* and delivered after forty-eight hours. She got up at the week's end, and a week after there was protrusion about the size of a walnut, which continued increasing till at present, *March* 20, 1842.—The bladder again protrudes between the *labia,* about the size of a crown piece; after standing up, the mouth of the womb descends behind; but both easily return when she lies down. Her health is now tolerable, and she manages with a little weariness to get through the usual occupations of a labourer's wife.

As with all the disadvantages which her continual standing whilst at the ironing board, the protrusion had been materially checked, and as she was capable of exertion which for some years before she was incapable of making, it may be inferred that the latter operation was advantageous to her, and that probably had she kept quiet at first for some months, she would have recovered completely. I should not hesitate therefore to perform this operation in a similar case.—J. F. S.

Lightfoot of Newcastle-on-Tyne (*a*) has performed successfully **Fricke**'s operation of episioraphy in a case of prolapsed bladder which descended through the *labia* to the size of a fist. Six strong hempen sutures were put in; the limbs tied together, and the woman put on her side; a catheter was introduced, and not removed for two days; but the urine being found to escape by its side, and cause irritation, it was removed, and passed occasionally for the following five or six days. Cold water was applied, and the *vagina* now and then cleared and washed by injecting cold water. Opium was given to constipate the bowels. Two of the sutures were taken out on the fourth, and the others on the sixth day, at which time union by the first intention was complete. Three weeks after the operation she left her bed, and walked about; and in a week after, she was able to resume her usual occupation of household work. On examining her three weeks after, there was not the slightest prolapse; and when she was desired to strain violently, the *rugæ* of the *vagina* were seen, but did not protrude.]

1295. *Prolapse of the Rectum* appears under three forms; it may be either the *rectum* with all its membranes, or simply the internal membrane, or an inverted upper portion of the intestine (*Volvulus, Intussusceptio.*)

Although the *rectum* is pretty firmly fixed in its place, its prolapse, with all its membranes, has been improperly doubted; it occurs rarely under this form, but I have distinctly noticed it (1).

[(1) The opinion here disputed is **Copeland**'s, who says:—"In almost every case of *prolapsus ani*, it is the *internal* membrane of the intestine only which descends through the *sphincter* muscle. The connexion of the external surface of the *rectum* is so firm with the surrounding parts, that it is almost impossible the whole should be protruded together; a separation or elongation of the union between the coats of the intestine must therefore precede the disease, and forms its essential character; whether it be produced by the effusion of blood between them, or by continued *tenesmus*, or efforts to pass the *fæces*, or peculiarity of structure, or any other cause." (pp. 74, 5.)

Syme does not agree with either **Chelius** or **Copeland**, as to what he calls *prolapsus ani*. He says:—"Such tumours consist either of the gut in its whole thickness, or of the mucous membrane alone in a state of morbid development. Being thus differently constituted, they should not be confounded together, as they usually are, but carefully distinguished, since they have no resemblance to each other, either in the nature of their production, or the treatment which they require. In making this distinction, it is fortunately unnecessary to employ any new names, since if the title *prolapsus* be confined to denote those protrusions in which the whole thickness of the gut is concerned, the other forms of the disease may all be referred to the head of Hæmorrhoids." (pp. 88, 9.)

Bushe describes only "two forms of this disease. In one the mucous membrane is alone prolapsed; whereas, in the other, all the coats of the *rectum* come down. The first is by far the most common, in consequence of the great extent and loose connexion of the mucous tunic; while the firm union of the intestine itself, with the surrounding parts, the longitudinal direction of its strongest and most numerous fibres, together with the action of the *levatores ani* muscles, offer much resistance to the descent of the entire gut." (p. 201.)

That cases do occur in which the whole gut is prolapsed, is put beyond all doubt, as **Velpeau** mentions, that "the younger **Bérard** dissected a tumour formed by invagination of the *rectum* through the *anus* of a female. The inversion of the intestine was complete, for the *peritoneum* was included in the swelling." (p. 128.) He also mentions **Paillard**'s case (*a*) and others cited by **Nelaton**.]

1296. In the prolapse of the internal coat of the *rectum*, consequent on relaxation and lengthening, merely a little reddish swelling first appears, which gradually enlarges, increases in size, becomes wider, is rounded below, but narrowed above by the *sphincter* muscle, and at its free extremity has an aperture by which the stools escape. The surface of the prolapse is, according to its different duration, and the degree of its

---

(*a*) Révue Médicale.

girting by the *sphincter*, red, bluish, more or less tense or soft, covered with bloody mucus, and often divided into several lobes (1).

In prolapse of the *rectum*, with all its coats, which I have only noticed in children, a more cellular swelling, which terminates pretty pointedly, projects directly, as in protrusion of the bowel from artificial *anus;* and if the finger be introduced through the opening, the contraction of the intestinal walls is distinctly felt (2).

The symptoms which prolapse of the *rectum* especially produce, are various, according to its degree and duration, but generally they are not severe, because the *rectum* is not so very sensitive to the contact of air. If, however, the prolapse be considerable, it may inflame or become strangulated by violent contraction of the *sphincter* muscle, in which case even gangrene may occur (3).

[(1) "When the mucous membrane is alone prolapsed in the child, it assumes," says Bushe, "the appearance of a small pyramidal, red and coiled tumour; while in the adult it is less red, and generally takes the form, either of two lateral flaps, or of a circular fold. In some of these cases, the portion of membrane thus protruded comes from the pouch of the *rectum*, while that within the sphincters remains *in situ.* When this is the case, we can pass the extremity of the little finger between that portion of the membrane which adheres to the internal *sphincter* and that which is protruded." (p. 204.)

(2) Syme's *prolapsus ani*, in which the whole thickness of the gut is involved, "consists of a tumour generally round or oval, but sometimes cylindrical, varying in size from that of a small egg to that of the largest orange, exhibiting the slimy surface of a mucous membrane, and affording a copious secretion of very similar appearance to red currant jelly. It is obvious that the connexions of the lower part of the *rectum* must prevent it from descending, so as to present these appearances, which can be accounted for only by supposing that the higher part of the gut becomes invaginated in the portion below it, so as to project beyond the *anus.* In short, the derangement will be the same as that which is named *intussusception*, with this difference, that, in the latter case, the invagination occurs higher up the intestine, beyond the reach of sight and touch." (p. 89.)

(3) "The symptoms of the *prolapsus*," observes Syme, "vary with the size of the part protruded, and the degree of vigour with which the intestine resents its unnatural position. They are, therefore, in general, more urgent in young persons, and less so in old people. There is always more or less uneasiness in the protruded part, and obstruction to the evacuation of the bowels; and, if inflammation commences, the sufferings of the patient become extreme, terminating even in his death, or mortification of the invaginated portion of intestine. Though the bad consequences are not always very rapid in their progress, the disease, if left to itself, can never be regarded as free from danger, and should, therefore, always be remedied as soon as possible." (pp. 91, 2.) Bushe also remarks that, "when the protrusion is allowed to remain down, it becomes engorged with blood from the pressure which the *sphincter* exercises on the veins, as is manifested by its increase in size and livid colour. If it be not soon reduced, inflammation sets in, and is attended not only with great local pain, but fever, and, in some rare cases, death ensues, in consequence of extensive peritoneal inflammation. In some other, and yet more rare cases, the protruding portion sloughs off, and a cure follows." (pp. 204, 205.) A case of the latter kind is related by Sauveur and Ansiaux (*a*).

Prolapse of the *rectum* is liable to be confounded with hæmorrhoidal tumours, and with *intussusception.* Copeland says "the *prolapsus ani* has so many points of analogy with hæmorrhoids, that it may, in some measure, be considered as the same disease in a more chronic and advanced state." (p. 73.) And Syme thinks that the protrusion of the mucous membrane alone should be referred to the head of hæmorrhoids. Bushe observes, as to its *diagnosis* from hæmorrhoidal tumours, that "the semilunar form of the flaps, the extent of their base, our ability to glide the folded membrane between the finger and thumb, as well as their freedom from erection and hæmorrhage, are characters so opposite to those which pertain to hæmorrhoidal tumours, that a very cursory examination enables us to distinguish them." (p. 162.) In reference to *intussusception*, he says:—"In protrusion of the *rectum*, we are not able to insert a probe or the finger higher than the border of the internal *sphincter*, in consequence of the doubling of the mucous membrane; while, in *intussusception*, no resistance is offered to the ascent of either one or the other." (pp. 205, 206.)]

(*a*) Ansiaux, N., Clinique Chirurgicale. Second Edition, p 179.

1297. The causes of this prolapse are either injuries which weaken the sphincter muscle and the natural attachments of the *rectum*, as infrequent hard evacuations from the bowels, the improper use of relaxing clysters or strainings, which drive the intestine down, as severe and continued bearings down in long continued *diarrhœa*, ascarides, hæmorrhoidal inconveniences, organic changes of the membranes of the *rectum*, stone in the bladder ; further, violent screaming and attempts at raising heavy weights, and the like. Rectal prolapse occurs most commonly in children, especially from *diarrhœa* during teething, and in old weakly subjects.

1298. Prolapse of the *rectum* is always a painful ailment. In children, it is for the most part, soon cured, if the causes of irritation of the *rectum* be removed, and more power obtained by the continued development of the sphincter muscle. In grown persons the disease is always more severe, and easily returns upon every occasion. In old prolapses considerable changes occur in the structure of the *rectum*, continued discharge of *mucus*, and the like, occur (1).

[(1) "When the descent of the bowel is often repeated," says Bushe, "the mucous membrane becomes indurated, loses its villous surface, and, in some instances, even ulcerates. This is more likely to be the case when the *sphincter* has become relaxed, from the repeated dilatation it has suffered, and there is a constant *nisus*, causing the bowel to contract, and force out the mucous membrane." (p. 205.)]

1299. The *treatment* consists in the reduction and keeping up of the prolapse and upon the removal of its causes.

For its replacement, if the prolapse be recent and small, slight pressure with the flat of the hand is sufficient ; but if it be considerable and have existed many hours, the patient must be placed, after having voided his urine, upon his belly, with the rump somewhat raised, and the thighs separated ; or he must be put upon his knees and elbows, and then with the finger smeared with oil, placed near the opening of the *rectum*, it must be attempted to press back alternately the part of the bowel nearest the opening, during which the patient should refrain from all forcing and shrieking. If in this way the prolapse be returned into the cavity of the *rectum*, it must be attempted by the introduction of the finger to carry it higher and into its original situation (1). If the prolapse be large, of many inches length, and consisting of all the coats, especially in children, the practice just recommended for its return is insufficient. The forefinger of the right hand must be introduced into the opening of the prolapse, with which the prolapsed part is to be thrust in and then kept up with the fingers of the left hand, placed at the edge ; the forefinger is to be somewhat withdrawn, and again introduced deeper, so as by repeated thrusting inwards to return the prolapse. If the reduction be very difficult, in consequence of spasmodic forcing, relaxing antispasmodic applications, opium internally and in clysters, are useful. If the prolapse be girt by the *sphincter* muscle, and much inflamed and swollen, its return must be attempted after the use of blood-letting and cold applications. Some persons recommend also slight cuts (2). If this do not succeed and symptoms of danger ensue,the *sphincter* muscle must be divided at that part where the stricture is greatest; by means of a director introduced into it, and a button-ended bistoury, which is advantageously preceded by the use of a *speculum ani*. If the bowel still cannot, on account of the great swelling, be reduced, it must be only gradually returned, as it is diminished by the use of proper remedies.

[(1) The plan recommended by Brodie for the treatment of prolapsed *rectum* in children is the following:—"Purge him with calomel and rhubarb occasionally; be very careful about his diet, that he does not eat a great quantity of vegetable substance, which tends to fill up the cavity of the bowel, while it affords but little nourishment, and every morning let some astringent injection be thrown up. That which I have generally used is a drachm of *tinct. ferr. mur.* in a pint of water, and two or three ounces or more of this, according to the age of the patient, may be injected into the *rectum* every morning, the child being made to retain it as long as possible. I never saw a case of *prolapsus* of the *rectum* in a child which was not cured in this manner." (pp. 845, 46.)

The treatment of prolapsed *rectum* in children, in whom it is frequently of considerable length, is a very troublesome matter. The attempt to reduce it gives the child pain, and causes him to cry, and thus force the bowel down repeatedly almost directly after its return, the relaxation of the *sphincter* being so great, in general, that it affords little opposition to the descent of the gut. I have not been in the habit of using injections; but have merely kept the child as much as possible in the horizontal posture, and, having returned the bowel, have applied a pad either of linen alone, or of cork covered with linen, and of corresponding size to the breadth of the protruded gut, fastening it with a T bandage. If the protrusion can be only a little restrained at first, it is pretty certain that continuing the same remedy will ultimately be effective, although but very slowly. Attention to the bowels, so that the stools should be thin, and passed with little effort, is a very important part of the proceeding; and for this purpose I prefer a teaspoonful of castor oil occasionally, which I think better than calomel, as less likely to produce the *tenesmus* so frequently following the use of that medicine. The nurse, however, must be taught how to return the gut, and strictly enjoined to return it immediately after the motion has been passed, and not to allow the child to sit straining on his chair, as is too commonly permitted.—J. F. S.

(2) Dupuytren, with great propriety, objects to this practice. He says:—"Some persons recommend scarifications; but, as they cause wounds, and consequently inflammation of the large bowel, they should not, as far as possible, be employed. The same objection applies to leeches, which may produce internal or external bleeding, and ulceration of the gut." (p. 159.)]

1300. In order to prevent the reprolapse, it must be endeavoured to get rid, as far as possible, of the causes upon which the disease depends, to diminish the irritation of the *rectum*, the bladder, or neighbouring parts, to extirpate hæmorrhoids and the like (1), and to restore to the *rectum* its natural powers by cold bathing, by cold or astringent clysters of red wine, and the like. To prevent the reprolapse, a piece of sponge dipped in cold water, is fastened with a T bandage, or the application of large strips of adhesive plaster, from the region of the *pubes*, near to the aperture of the *anus* up to the region of the rump-bone, so that merely a space is left for the passage of the stools (*a*); the bandages of Juville (*b*) and Gooch (*c*), are to be preferred, as most suitable; as also the application of a pad of lint, in such way as not to prevent the discharge of the stools, a hollow cylinder of ivory or of caoutchouc, by which it is hoped to keep the relaxed walls in their proper place, but which generally cannot be worn, and still further weakens the *sphincter*. In women, the prolapse of the *rectum* may be kept back by a pessary introduced into the *vagina*, only it must not press either too much or too little upon the *rectum*.

Klein (*d*) recommends, as a very efficient remedy, even in very old prolapses of the *rectum*, sprinkling a powder, consisting of equal parts of gum arabic and *colophonium*; by the use of which the prolapse returns, and this is to be repeated as often as the prolapse recurs. I have not, however, noticed any particular benefit from it. Schwarz (*e*) recommends the extract of *nux vomica*, as a very efficient remedy in all cases of *prolapsus ani*, one to two grains dissolved in two drachms of water, of which from six to ten drops are to be given every four hours to children; and to older persons, even fifteen drops; frequently he gives it in connexion with some grains of extract of rhatany.

[(1) When an adult labours under prolapse of the *rectum*, "consequent on a protrusion of piles, the first thing to be done," says Brodie, "is to destroy the piles. Let the patient sit on a pan of hot water, and the *sphincter* muscle being relaxed, and the parts distended with blood, the piles and *rectum* will all protrude together. You must then tie the piles, which you can easily do, your assistant holding the *rectum* on one side, while you apply the needles and ligatures on the other. Having tied the piles, you return the *rectum* into its proper place; and you will probably find that, in curing the piles, you have also remedied the *prolapsus* of the bowel; but, if the patient neglects himself afterwards, as the piles return, so the *prolapsus* returns with them." (p. 846.)]

1301. All these modes of treatment are, for prolapse of long standing, really fruitless, and accompanied with considerable inconvenience to the patient (1). In these cases, the treatment prescribed by Dupuytren (*a*) is most effective; the patient is put upon his belly, his head and shoulders low, but his *pelvis* on the contrary much raised by one or several pillows, for the purpose of rendering the aperture of the *anus* more distinct. Two, three, four, five, or six, of the radiating folds surrounding the *anus*, which are either level, or more or less prominent, are to be seized with a pair of pincers, with somewhat flattened points, one after another, right and left, and even before and behind, and each fold, as raised, is to be taken off with scissors curved towards the surface, and the cut is then to be continued to the *anus*, or even higher into it; but it is ordinarily necessary only to continue the cut some lines upwards. In less relaxation, two cuts, in greater relaxation, several cuts are to be made on each side. Bleeding and other symptoms do not come on; but usually during the operation there is violent contraction of the *sphincter*. The wound is to be simply treated, and after scarring, the opening of the *anus* has proper firmness, and the prolapse does not recur (2).

The application of the actual cautery, according to Phillips (*b*), corresponds in its operation to excision: according to the state of the case, from one to four applications must be made; and indeed, if the disease be recent, it may be merely applied to the edge of the *anus*, without touching the mucous membrane of the *rectum*; but if the case be old, the white-heated iron must be carried over the mucous membrane. The length of the slough should be half an inch. Scarring produces such contraction of the *anus*, that reprolapse is thereby prevented.

[(1) The difficulty, and even impossibility, of returning the bowel sometimes occurring in old prolapse of the *rectum*, does not depend on the contraction of the *sphincter*, as might be supposed. This was first noticed by Hey, who observes:—"Although the prolapsed part of the intestine consisted of the whole inferior extremity of the *rectum*, and was of considerable bulk, yet the impediment to the reduction did not arise from the stricture of the *sphincter ani*, for I could introduce my finger with ease during the *procidentia*; but it seemed to arise from the relaxed state of the lowest part of the intestine and of the cellular membrane which connects it with the surrounding parts." (p. 424.)

(2) It has been disputed whether Dupuytren is to be considered as the originator of this operation, or whether it is merely a modification of Hey's. There can be no doubt that the principle was the same, that of diminishing the aperture of the *anus*; but the two operations differ from each other as much as Copeland's presently to be described, and far preferable to either, differs from both. Hey's account of his operation will show its total difference from Dupuytren's; and that able French Surgeon is fully entitled to the merit of whatever credit belongs to its proposal; although I must confess I think Copeland's operation is best of the three recommended. Hey says:—"The relaxed state of the part which came down at every evacuation, and the want of sufficient stricture in the *sphincter ani*, satisfied me that it was impossible to afford any effectual relief to my patient, unless I could bring about a more firm adhesion to the

Glasgow, 1832. p. 151.

(*b*) London Medical Gazette, vol. xi. p. 384.

surrounding cellular membrane, and increase the proper action of the *sphincter*. Nothing seemed so likely to effect these purposes, as the removal of the pendulous flap and other protuberances, which surrounded the *anus*. I hoped the inflammation caused by this operation would produce a more firm adhesion of the *rectum* to the surrounding cellular substance; and I could not doubt that the circular wound would bring on a greater stricture in the *sphincter ani*." (pp. 443, 44.)

It is not out of place to remark in reference to these operations, that Velpeau observes:—"Very frequently a portion of the fleshy coat of the intestine is found accompanying the mucous coat in prolapsed *rectum*. There is no inconvenience in removing with the mucous membrane a portion of the muscular tissue; on the contrary, the cure will be more complete, and I have some disposition to believe that the want of success which has occasionally followed the operation has depended on the omission of this precaution." (p. 135.)

The only means of "restoring the disturbed union between the inner membrane of the intestine and its external surface," is, according to Copeland, "by exciting a degree of inflammation on the *external* surface of the inner membrane, sufficient to produce an union and consolidation of the parts together." He objects to the use of stimulating injections, as inflaming the mucous surface, causing great pain and distress, "without any material benefit to the disease; for the inflammation is propagated along the mucous surface, without extending to the deeper seated parts or external coat of the intestine." Having shown that the inner coat of the alimentary canal loses a considerable portion of its villous nature as it approaches its extremities, that wounds at such points are less serious than when inflicted on the more interior portions of the canal, and that "the degree of pain is beyond all comparison, less in proportion as the part wounded or tied is more removed from the *anus* and the *cutis* surrounding it; an operation or ligature which would be violently painful at the circumference of the *anus* if it involve the smallest portion of the skin, being spoken of as little more than uneasiness, or not calling forth any expression of pain, when performed on a part of the membrane more removed from the seat of external sensation; and the consequent fever and inflammation having the same relation to the part," he proceeds to observe, that "the only effectual means then of producing this desirable union between the coats of the intestine, is by a wound, or a removal of a small part of the inner membrane which protrudes at the *anus*, and constitutes the disease." * * * That the removal of the (entire) protruded portion is not very essential to the cure of the disease, I think will appear evident, if it be considered how very small a part of the inner membrane being cut or tied away, in proportion to the whole bulk, will be sufficient to prevent the remainder from protruding. I have, in some instances, been obliged to repeat the operation on the opposite side of the gut, when the adhesion formed by the wound was not sufficient to support the whole circumference of the canal. But in one case I removed the ligature immediately after it had been very tightly applied, and returned the intestine. The cure was complete; but I do not know whether the part sloughed or not to which the ligature had been applied. This injury done to the inner membrane of the intestine, then, is the most certain mode of producing that degree of inflammation, and consequent adhesion, which produces the cure of the disease, and in which, in fact, the cure consists.

"The mode of performing the operation which I think is most advisable, and which I have very frequently performed without any one unfavourable circumstance, is, the bowels being well emptied previously, and the time chosen when the projection is considerable, to pass a tight ligature round a very small portion of the inner membrane, at a part not immediately in the vicinity of the *anus*, that is, above the union of the *cutis* with the mucous membrane, and to return it, together with the ligature, into the gut. This is not, for the most part, a painful operation; but it is advisable that a grain of opium, or a few drops of laudanum, be given to procure ease, and also that the bowels may be somewhat confined for a day or two after the operation; for an evacuation during the active stage of the inflammation would give considerable uneasiness, and interrupt the adhesions which we depend on for the cure. Nevertheless, the cure has not been less complete, because the parts have come down in a more swelled and painful state for several days after the operation. The patient must be directed to keep his bed, should live very sparingly, and cloths dipped in Goulard water, or laudanum and water, should be applied when the pain or inflammation require it. In two or three days, if the bowels have not acted spontaneously, some mild aperient should be given. In about five or six days the ligature comes off, and shortly afterwards the part will heal, and cease to come down, or come down only in a much less degree than before the operation." (p. 77–84.)

This mode of treating prolapse of the *rectum* is now pretty commonly employed; and from my own experience, I may add that COPELAND has very faithfully and truly described its simplicity, its almost entire freedom from pain, and its great advantages. I have never had occasion to perform HEY's operation, or its modification by DUPUYTREN; and I believe that in almost all cases COPELAND's method will be found amply sufficient, and infinitely less painful.—J. F. S.

M'CORMAC says (*a*), that "reflecting on the procedure in question, (DUPUYTREN's operation,) it occurred to him that the same result might in a measure, at least, whilst the child went to stool, be secured by careful manual traction. * * * Accordingly when the child went to stool, the skin, anterior to the *anus*, was drawn to one side by means of the fingers extended around. The little girl submitted to this with some reluctance, and complained that she could not evacuate her bowels. She was encouraged, however; a stool was obtained; from that day and date, now a month since, the bowel has not once descended. * * * The little girl requires comparatively little attendance, her mother, in fact, is only required to stand by, and in a short time, it is to be hoped, her onerous and anxious ministry will wholly cease." (p. 417.)]

1302. In an old prolapse of the *rectum*, a considerable enlargment, and and at last hardening of the prolapsed part, is often gradually produced by the contact of the air, rubbing, and so on. If in such case the return be not possible by continued supine posture, by keeping up pressure and the use of cold applications, or if doubtful symptoms arise, the protruded part of the *rectum* must be cut off at its base. In doing this considerable bleeding is always to be feared, for which plugging, employed in the way prescribed, (*par.* 939,) is no certain remedy, as it is easily thrown off, or displaced, by violent forcing, and, as I have seen, fatal bleeding ensues. It is preferable, after the removal, to touch the bleeding part with the actual cautery, by which the bleeding is more certainly stanched, and the elastic power of the *rectum* increased. In order to meet the danger of bleeding in cutting off a degenerate prolapse of the *rectum*, SALMON (*b*) has proposed the following proceeding, which he has found by experience to be sufficient. The patient being properly placed, and the buttocks separated from each other by an assistant, he thrusts one or more stout straight needles from above downwards, through the base of the swelling. As the needles penetrate the muscular coat, they prevent its return after the tumour is cut off. He now takes hold with the hook, or with forceps, of a portion of the swelling, draws it gently towards the opposite side, and cuts it off with one stroke of the scissors, as deep as the line between the mucous and muscular coats, which must be spared, as otherwise there will be slight difficulty in going to stool. In the same way all the other portions are to be removed. After the removal, the bleeding is to be stanched by the usual means; cold water is usually sufficient; most commonly it stops of itself. If the vessels are to be tied, it may be done easily, as the wounded surfaces are kept out by the needles. The needles are to be left in for an hour; and the wounded surface should be anointed with oil.

In irreducible prolapse, which causes severe and dangerous symptoms, the application of the actual cautery was early recommended by LEONIDAS, SEVERINUS, TULPIUS, LEVRET, and others.

[The use of the actual cautery to produce sloughing of an obstinate prolapsed *rectum* was recommended by ANSIAUX (*c*) in consequence of the cure he had noticed to result after a natural slough of the protruded gut; he operated on three women at the different ages of sixty-two, thirty-five, and sixty years, with success. DUPUYTREN objects (*d*) to the cautery, that "independent of the severe pain it causes, it may produce violent and more or less serious inflammation of the intestine and of the neck of the bladder." (p. 161.)]

(*b*) Practical Observations on Prolapsus of the Rectum. London, 1831. 8vo.

(*c*) Above cited.

(*d*) Above cited.

1303. The prolapse of an ensheathed upper intestine, of the lower end of the *colon*, of the *cæcum*, even of the *ileum*, is usually distinguished by its having some inches of length, and by its condition. The only aid consists in the return of the prolapsed part into the *rectum*, and in keeping it up. If the finger be insufficient for its return, an elastic tube, and even the dashing of cold water (BOYER) must be used. A very large portion of ensheathed intestine of considerable length has been observed to separate and to be thrown off.

[In connexion with prolapse of the *rectum* it may be well to notice here two conditions mentioned by BUSHE.

1. *Relaxation of the Anus,* which "depends upon a want of contraction in the sphincters the causes of which are:—disease or injury of the brain or spinal cord, exhaustion attending weak health, sedentary habits, protracted diseases or old age, excessive or repeated dilatation of the *anus*, produced by straining in chronic dysentery, the introduction or extraction of foreign bodies, and the growth of tumours from within the intestine, and finally operations performed for fistula, fissure, &c. The consequences of this affection are proportionate to the want of power in the sphincters; thus, when they are completely paralysed from disease, or injury of the brain or spinal cord, the *fæces* are discharged involuntarily; whereas in that diminution of tonicity in their fibres, which depends upon constitutional exhaustion, the discharge of *mucus*, attended perhaps with slight excoriation of the verge of the *anus*, is the most troublesome symptom. It not unfrequently happens that the mucous membrane is protruded, and should the dilatation be considerable and prolonged, especially in elderly persons, the surrounding skin will lose its elasticity, which it is not very apt to recover, even though the sphincters be restored to their primitive condition." The treatment will depend upon the cause; if the brain or spinal cord be at fault, these must be looked to; if there be hæmorrhoidal or other tumours, they must be removed; and if the general health be impaired, it must be improved. "The best local remedy," says BUSHE, "is the injection of half a pint of cold water, three times a day." Stimulating vapours and compresses dipped in astringent washes are recommended by some practitioners. (pp. 213, 14.)

2. *Relaxation of the rectum with invagination of the mucous membrane* "is disposed to by repeated distension of the bowel with *fæces* or injections. When the *rectum* is empty or relaxed, and the individual strains violently to effect a motion, the mucous membrane may be forced into the inferior part of this intestine, and thus partially obstruct it, so that the fæcal matter lodged above can be but imperfectly discharged. If the finger be introduced, the nature of the case will be easily discovered. The bowels are confined; the calls to defecate are frequent, urgent, and generally ineffectual, nothing being voided but mucous or puriform matter, often streaked with blood; finally, the pain is always considerable, but occasionally violent. A well-regulated diet, gentle aperients, emollient followed by astringent injections, and the use of the inflated gut or bougie will generally suffice for its removal. If, however, the nature of the case be not detected, one of two things must follow: either a complete *prolapsus* will ensue, or what is worse, the displaced membrane will, from irritation and inflammation, become thickened and indurated, and the opening through it contracted." (p. 215, 16.)

The case quoted by SALMON, and which was under the care of SOMME (*a*), appears to me to have originated in this relaxation, though the young woman is stated to have been "long affected with a contraction of the *rectum*, three or four inches above the *anus;* and the bridle forming the ring, hard, callous, and so contracted, that it only allowed liquid matters to pass, whence arose obstinate constipations and colic;" for SOMME continues:—"I tried dilatation with bougies, which had momentary success." Now if a stricture had formed, the bougie would not have passed, but if, as seems probable, the obstruction was caused by the descent and ensheathing of the mucous membrane, the introduction of the bougie would carry it up and unfold it, and thus the obstruction be got rid of for the time. That this was really the case seems to be proved by her becoming attacked some time after with severe constipation, which lasted three weeks, accompanied with vomiting, swelling, and pain in the belly, violent colic and fever. She was treated for *enteritis*, the constipation overcome with clysters, which were followed by copious sanguineous *diarrhœa*. Subsequently the evacuations became free, the fever ceased, and some days after "a piece of membrane protruded

---

(*a*) Etudes sur l'Inflammation. Paris, 1830. 8vo.

by the *rectum*, which being slightly pulled, brought away a portion of intestine about a foot long. This was not false membrane, but wholly intestine; internally the villous coat was black, externally the surface was smooth, and there was a groove upon it indicating the attachment of the mesentery."

SALMON makes a very good observation in reference to the incautious use of clysters, which have been noticed as one cause of relaxed *rectum*. "Many persons," says he, "are daily in the habit of throwing immense quantities of fluid into the *rectum*, by which it is forcibly distended and irritated; thus, instead of the enema affording relief, it is productive of serious irritation; but a far greater evil resulting from this practice is, that the *rectum*, from the immoderate distension thus induced, is rendered unsusceptible of the natural stimulus arising from the *ordinary* accumulation of fæculent matter;" and in support of this statement he relates a case of supposed stricture of the *rectum*, in which he passed number eleven bougie without difficulty, to the great surprise of the patient, who for some time had lost nearly all power of relieving the bowels which never acted without the assistance of medecine or an enema, "he having been in the habit of pumping a couple of quarts of thin gruel into the intestine once, and occasionally twice every day." (pp. 23, 24.)]

BLUNDELL, JAMES, M.D., above cited.

RIGBY, EDWARD, M.D., on Retroversion of the Unimpregnated Uterus; in his Reports on Diseases of Females; in Medical Times, vol. xiii. 1845.

1304. The womb is subject to various changes of direction, inasmuch as its axis may deviate backwards, forwards, or to either side from that of the *pelvis*. The former two states only will be here specially considered.

1305. If the long axis of the womb vary so much from that of the *pelvis*, that cutting it at a more or less acute angle, its base be directed towards the rump-bone and the mouth of the womb towards the share-bone, this displacement is called *Retroversion of the Womb* (*Retroversio Uteri*, Lat.; *Rückwärtsbeugung der Gebärmutter*, Germ.; *Rétroversion de la Matrice*, Fr.); but if its base drop towards the share-bone, and the mouth of the womb be inclined towards the rump-bone, it is called *Antroversion* (*Antroversio Uteri*, Lat.; *Vorwärtsbeugung*, Germ.; *Antroversion*, Fr.) The former position is more frequent than the latter, and both may occur to a greater or less extent.

1306. *Retroversion of the Womb* occurs more frequently during pregnancy, especially in the third and fourth months, than in women not pregnant; it is, however in these often enough, and (according to SCHWEIGHAEUSER and SCHMITT (*a*)) even more frequent than during pregnancy; and my own observations on this point concur with that opinion.

[RIGBY is also of this opinion, and observes:—"I am sure I have the confirming testimony of Dr. SIMPSON and Mr. P. SMITH when I state it to be one of the most common displacements to which the *uterus* is liable in the unimpregnated state, and that this form of it occurs *far more* frequently than the ordinary retroversion during pregnancy," (p. 124.) There is, however, a difference between the retroversion which occurs whilst the woman is pregnant, and that when she is not so; for RIGBY observes:—"The case now alluded to is where the *fundus* is bent downwards and backwards; so that it can be felt close behind the *os* and *cervix uteri*, which, instead of being forcibly dragged upwards and forwards behind the *symphysis pubes*, is little, if at all, removed from its natural situation. This state of retroflexion (a term which RIGBY prefers to retroversion, J. F. S.) is chiefly met with in the unimpregnated *uterus*, although it sometimes occurs during pregnancy." (p. 124.)

"In different women," observes BLUNDELL, "the womb varies very much in its virgin size; for in some it is three times as large as in others. Now if it so happen that the womb is very small, and that retroversion has taken place without impregnation, the pressure which it occasions may be so inconsiderable, that the nature of the case may remain unsuspected; but when the womb, though unimpregnated, chances to be of large size, especially if the *pelvis* is small, or contracted, considerable pressure may be produced, and we are first led to investigate its nature, in consequence of the irritation and obstruction of the *rectum* and the bladder, when the accident is soon recognised by the characteristics before given." (p. 19.)]

1307. It is probable that retroversion of the womb in pregnant and not pregnant women is not produced at once; but by degrees, under favourable circumstances, a complete retroversion is gradually formed from a simple reclining of the womb. The following may be noticed especially as predisposing causes, slight inclination and great capacity of the *pelvis*, low position of the intestines, perhaps also DOUGLAS's folds, peculiar deviation of the original formation (*b*), relaxation of the broad and round ligaments of the womb. The occasional causes are, pregnancy, overfilling of the urinary bladder, stools unfrequent or accompanied with great effort, constant lying on the back, increased weight, swelling, or other degeneration of the hinder wall of the womb, violent straining, and so on.

Retroversion cannot occur in a perfectly healthy state of the womb; were it even possible, it could not readily produce such severe symptoms. The chronic inflammatory state of the womb, which most commonly gives rise to retroversion, causes pain and dragging in the back and loins, difficulty in walking, difficulty in voiding the urine and in going to stool. On examination, a lower position of the womb, swelling and

---

Zeitung, 1808, vol. iv. p. 170.—BRÜNNINGHAUSEN; in VON SIEBOLD's Journal für Geburtshülfe, Frauenzimmer- und Kinderkrankheiten, vol. iii. p. 59.—SCHWEIGHAEUSER and SCHMITT, above cited.

(*b*) SCHREGER; in HORN's Archiv. 1817, March and April, p. 311.

sensibility of its vaginal portion are observed; most commonly also is there a flow of *mucus* from the generative organs. The two last symptoms distinguish it from pregnancy (*a*).

1308. The symptoms which indicate retroversion of the womb depend on the obstructed or completely suppressed discharge of the urine and stools, and on the diseased changes which arise in the displaced womb. These symptoms in general occur suddenly in retroversion during pregnancy, which greatly prevents and often entirely suppresses the voidance of the stools and urine; severe and extremely painful dragging come on with a feeling of pain, weight, and fulness of the belly, also distension and painfulness, disposition to vomit and actual vomiting, fever, extreme restlessness, abortion, and even death from tearing of the bladder, and inflammation and gangrene of the intestines of the belly (*b*).

The seeming retroversion of the womb, mentioned by Mende, must be noticed, in which case at the later periods of pregnancy, its hinder wall expands like a sac, producing similar symptoms to the true prolapse, usually terminates in abortion, and is distinguished by the mouth and neck of the womb not at all deviating from their natural position (*c*).

[(1) Blundell observes, that "the patient often tells her adviser that she has been placed in some situation of restraint, and that afterwards, on retiring, and trying to evacuate the contents of the bladder, not a drop of the secretion would pass away, and this has occurred perhaps for hours before you see her, the accumulation having continued ever since; so that there is a great deal of pain of the *abdomen* and heat, with forcing and fluctuation, which may be felt as distinctly as in a case of *ascites*. I wish it to be understood, however, and very important it is that this should be known, that in the retroversion of pregnancy, you have not always, nor I think generally, these *complete retentions* of urine; for often, where the *uterus* is retroverted, the retention is partial. In a case recorded by Van Doeveren, although the woman passed her urine every day, still she died from a ruptured bladder. * * * Day after day the fluid is sparingly emitted, but never in such quantity as to empty the bladder completely, till by-and-by, perhaps, the secretion begins to steal away involuntarily, or she may have strong efforts to pass the urine, even against her will, and with every effort a small gush only may be produced, or there may be a continual dripping, and yet, notwithstanding all this, an accumulation of water may go on very gradually, so that several pints, nay, several quarts, may be gradually accumulated, as in the following example:—'A woman labouring under symptoms like *ascites*, a practitioner proposed, I think, the operation of tapping. There was, however, some obscurity about the case—a great deal of pain more especially—and, an obstetrician being called in, in consequence, a catheter was introduced, and water drawn to the amount of seven quarts, which had been accumulating in the bladder for two or three weeks, in consequence of a retroversion of the *uterus*.'" (pp. 7, 8.)

(2) Lacroix remarks (*d*) that, whether by sympathy or direct irritation, is not so evident; but it is often seen, nevertheless, that when the retroversion is sudden, either in the virgin, or pregnant female, hiccup, flatulence, vomiting, fainting, &c., commonly show themselves; and, even when the displacement is more gradually produced, analagous symptoms of less intensity are present.]

1309. On examination with the finger in the *vagina*, the mouth of the womb is found behind or above the share-bones; often scarcely, some-

(*c*) On Retroversion of the Womb after birth, with tearing of the hind wall of the *vagina* and prolapse of the *fundus uteri*.—See Dubois; in Presse Médicale, May, 1837. No. 20.—Schnackenberg; in Casper's Wochenschrift, 1838. No. 34–35.

(*d*) Annales de la Chirurgie, vol. xiii. p. 457, 1845, April.

times not at all reachable, and on the hind wall of the *vagina* is the *fundus* of the womb, descending against the rump-bone like a lump, which on examination is felt through the *rectum.*

[" In examining a case of retroflexion of the unimpregnated womb during life, the finger," says RIGBY, "can frequently reach a firm globular mass like a walnut, situated behind the *cervix uteri,* and evidently posterior to the *vagina.* At the first touch, or to one unacquainted with this condition of the womb, it seems like a lump of scybalous matter in the *rectum ;* for in many, perhaps most instances, the finger cannot reach sufficiently high up to distinguish the continuity of this mass with the *cervix,* the point of flexion being usually in the body of the *uterus,* close above its junction with the *cervix.* This, however, varies considerably, both in different cases and in the same individual, and at different times. In some cases the curve is much higher, so that the whole of the *uterus* seems to be in the natural position, except a sharp bend or double at its uppermost portion. In others, the point of flexion is so low down that it can be easily reached, and the *fundus* is felt much lower than the *os uteri.*

" On examination *per rectum* we feel the same hard lump through the anterior wall of the intestine; and by being able to reach higher up in this direction than with the finger *per vaginam,* we can frequently verify or correct our first impression. But it is by the uterine sound, invented by Professor SIMPSON, that we obtain such peculiarly valuable and interesting results in this form of uterine displacement. On passing the instrument in the usual direction upwards and forwards, it becomes almost immediately arrested; but on turning its point backwards, exactly in the contrary direction, it will pass readily along the *cervix,* and then glide downwards and backwards, until the measure mark of two and a-half inches having reached the *os uteri,* shows us that it has entered to the natural extent of the uterine cavity; the point is now evidently in the centre of the tumour between the *rectum* and *vagina,* as may be felt through either of these passages, thus proving it to be the *fundus uteri* in this unnatural position. By carefully turning the instrument round, and carrying its point upwards and forwards in the natural direction of the *uterus,* we shall also carry up the *fundus* upon it and restore the *uterus* to its proper position. On examination either by the *vagina* or *rectum,* we now find the tumour has entirely disappeared; and as far as the finger can reach through the latter passage, the *uterus* will be felt in a direction upwards and forwards, and held in that position by the sound within it. In some instances the *uterus,* when once replaced, maintains its natural position either permanently, or at least for some little time afterwards ; but in many, especially those of long standing, and where the *fundus* has been forced very low down, the handle of the sound requires to be held firmly so as to keep the *uterus in situ ;* and the moment we loose our hold of it, (the handle,) it will turn round, rising at the time upwards and forwards towards the *symphysis pubis,* showing that its point has turned downwards and backwards. In other words, the *uterus* has returned to its former state of displacement, carrying the sound along with it; we shall now again feel the tumour in the recto-vaginal sac, containing the point of the sound within it.

" On examination *per vaginam* we shall find that pressure on the retroflected *fundus* seldom produces pain until we try to push it up against the ovary; the sound will pass into the *fundus* without causing much uneasiness, but if we carry the finger to the upper parts of the *vagina* into the vicinity of the ovary we shall excite severe pain. The same will be observed in examination *per rectum:* the instant we press up the *uterus* the patient complains greatly, but *per se* the *uterus* is not painful, and we can ascertain that the intensely painful spot is distinctly above the tumour formed by the retroflected *uterus.* These and other symptoms resulting from ovarian irritation or inflammation cannot, therefore, be looked upon as a necessary accompaniment to retroflection, although there is no doubt that they are frequently present; but the two affections are sufficiently often associated to justify a careful examination of the position of the *uterus* in every case of chronic *oophoritis.*

" In some cases the canal of the *cervix* is so closed at the point of flexion as to resist every attempt to introduce the sound, and the dilator must be carefully premised until a sufficient passage has been obtained. I have reason, however, to think that when the canal is so closed as to require the dilator, it is rather owing to a congenital formation than to the effects of the bent state of the *uterus,* which last is, however, sufficient not only to obstruct the free discharge of the *catamenia,* but also to prevent conception." (p. 125.)]

1310. The symptoms do not occur so quickly in retroversion of the womb in women who are not pregnant, and vary according to the degree of retroversion and the condition of the womb. Only with slight reclination and little sensibility of the womb do no symptoms occur; if there be much sensibility, dull pain occurs in the bottom of the *pelvis*, dragging, painfulness on examination, sometimes difficulty in the discharge of the urine and stools, and gradual organic changes in the womb. In a greater degree of reclination, swelling up of the whole womb is observed, but especially of its hind part with increased sensibility to the touch; increased weight and difficulty in moving about. The sensation of constant pressure in the region of the *rectum*, with difficulty in voiding the stools and urine. In completely retroverted womb dragging pains, swelling, weight, immobility of the womb, often inflammation and great painfulness on examination, suspended or irregular menstruation, and difficult voidance of the urine and stools occur. If the retroversion take place after delivery, it may cause continued and dangerous flooding (*a*). It is self-apparent that these symptoms must be variously modified by the simultaneous changes in the structure of the womb, and that examination must demonstrate a different relative position of the mouth and base of the womb, according to the different degree of displacement. If the womb be fixed in its unnatural position by adhesions, the retroversion may even be fatal from the inflammation of the intestines lying in the *pelvis* (*b*).

["The presence of this displacement is not necessarily indicated," says RIGBY, "by any peculiar symptoms; indeed, in some instances, I have found it existing without a single circumstance to make the patient suppose that she was otherwise than in a state of the most perfect health, even as regards the catamenial periods. Generally speaking, however, there is a dull pain and sense of pressure about the *sacrum*, verging to one side or the other, according to the direction which the *fundus* has taken. In some instances she has pain and numbness down the thigh of that side, with difficulty or inability to move or stand upon it, and probably arising from the *fundus* pressing on some of the sacral nerves, since the pain is instantly removed by the replacement of the *uterus*, and the numbness or lameness ceases in an equally striking manner. At times this pressure increases to a severe bearing down, which after a while again subsides, and which is probably connected with the passage of *fæces* along the neigbouring intestines, and more or less depressing the *fundus*.

"In a considerable number of cases there are distinct marks of ovarian inflammation on the side to which the *uterus* inclines; or at any rate I may say that, in a large majority of cases, as it is the left side to which the *uterus* inclines, so is it also the left ovary which is most frequently painful. These are, in fact, the ordinary signs of *oophoritis*." (p. 125.)]

1311. As to *prognosis*, the bad symptoms have been already mentioned which especially occur in retroversion. It must be especially observed in not pregnant women, whether the organic changes of the womb be preceded by retroversion, or whether they be consequent on it; in the former case the restoration of the proper position of the womb is the most perfect cure, but in the latter not.

["With respect to the prognosis of retroversion," BLUNDELL remarks, "that where the womb is replaced, the patient, in general, does well enough, provided you proceed on the principles prescribed; yet it is not impossible that miscarriage may take place after reduction; for in two or three instances I have known this take place. Inflammation of the bladder of the acuter kind may occur, and you may have a chronic disease of this organ. Where there is a good deal of inflammation, your patient may die of exhaustion. You may find that some officious hand has thrust a catheter through the back of the bladder into the *peritoneum*, and that the escape of the urine into the *peritoneal* sac has destroyed the patient. The bladder in some rare cases may be burst

---

(*a*) BRÜNNINGHAUSEN, above cited.

(*b*) SCHWEIGHAEUSER, above cited, p. 253.—SCHMITT, above cited, p. 16.

open, of which I possess a very beautiful preparation. The *uterus* is as large as a child's head; above the retroverted *uterus* is the bladder which has been ruptured. It is remarkable that in this rupture of the bladder, which has arisen from its over distension, it is not the front, that surface of it, I mean, which has no *peritoneal* covering, but it is the posterior surface, invested by the *peritoneum*, the back part of the body, which is the region of the rent. Now it was this which first led me to propose, that where a rupture of the bladder takes place in any case, but especially in a retroversion of the *uterus*, we should not give the patient up for lost; for if there is reason to believe that the bladder is burst into the *peritoneal* sac, we might make an opening into the *peritoneum*,—say above the *symphysis pubis*,—by which we might discharge the urine, and then injecting distilled water, of the temperature of 98°, we might wash the *viscera*, so perhaps as to prevent a general *peritonitis;* this done, we might draw the bladder up to the opening, and close the rent by ligature. This operation I have performed on several rabbits; in one or two experiments I brought the bladder out, tied it up, and took away about one quarter of it, viz., the whole of the *fundus*, and the animal did perfectly well. This operation I have never had occasion to try on the human subject; but in a case otherwise desperate, I should be inclined to recommend it. I may here remark, that since I have suggested this method of closing the bladder by ligature, Mr. Travers (*a*) has performed the operation on the stomach; there was a slight wound in the organ; he boldly tied up the aperture; the thread came away, and the case did perfectly well." (pp. 19, 20.) It must not be supposed that Travers made the ligature on the wounded stomach from Blundell's suggestion; Astley Cooper had long before tied up the hole in a gut, wounded during the operation for strangulated rupture, and the case did well. Travers himself had also, some years before Blundell's proposal, considered the matter, related experiments on the subject, and laid down rules for the application of the ligature. But Benjamin Bell had mentioned this question even long before Travers (*b*).]

1312. The *treatment* of retroversion of the womb consists in emptying the bladder and *rectum*, and on the restoration of the natural position of the womb.

1313 Emptying the bladder is effected by the introduction of the catheter, which is rendered easy if with two fingers of the one hand, that part of the *vagina*, opposite the pubic *symphysis*, be smoothed and pushed upwards, or if its more elevated position forbid this, if it be merely pressed backwards. This manipulation is not without advantages even if the entrance of the *urethra* be so much drawn inwards, that it cannot be seen, or if any other obstacle to the use of the catheter exist (*c*). When drawing off the urine is completely impossible, puncturing the bladder above the *pubes* has been proposed (*d*).

Emptying the *rectum* is to be attempted with clysters (which can often only be done with difficulty) of decoction of barley and grass roots, with the addition of salt. Experience shows that in many cases, after this previous treatment, the retroverted womb of itself recovers its position (*e*). Hence by many, the replacement is considered unnecessary, and the distensions of the bladder and *rectum* held as the special cause of the retroversion. If inflammatory symptoms be also present, they must be attacked with suitable treatment.

1314. The modes of proceeding for the replacement of the retroverted womb are very various. The patient being placed on her knees and elbows, the base of the womb is to be pressed forwards and upwards towards the navel, with two fingers introduced into the *rectum* (*f*); which manœuvre may perhaps be assisted by two fingers passed into the *vagina*, and

(*f*) Hunter, W., Saxtorph, Richter, and others.

attempting to draw down the mouth of the womb. Some recommend the replacement to be effected by the fingers (*a*) introduced into the *vagina*, and in difficult cases, even the whole hand (1). The difficulties which have occurred in certain cases have led to the use of elevating instruments (*b*), to the proposal of puncturing the womb (*c*) (2), of cutting through the pubic *symphysis* (*d*), and of opening the belly (*e*).

(1) **Bellanger** (*f*) advises, when, on account of the elevated and forward direction of the neck of the womb, it is not possible to employ the fingers through the *vagina*, to introduce a flattened catheter into the bladder, and therewith to bring down the neck of the womb, whilst with the fingers in the *rectum*, its base is lifted upwards. This object was effected in a case where attempts at replacement had been vainly made in different ways. See also **Lallemand** (*g*).

(2) Puncturing the base of the womb through the hind wall of the *vagina* has been successfully performed by **Jourel** of Rouen. **Baynham** (*h*) has performed it successfully, by a curved trocar passed through the *rectum* into the most projecting part of the swelling.

Halpin (*i*) effects the replacement, by inflating a bladder introduced into the *vagina* in the following manner. "I attached," says he, "a small recent bladder to the tube of a stomach-pump, with an air-tight piston, and, having immersed it a few moments in warm water, to bring it to the heat of the body, I introduced it, empty, into the *vagina*, between the *fundus* of the *uterus* and the *rectum*. Retaining it within the *vagina*, by holding my hands firmly across the orifice, it was then slowly and steadily inflated. After a time she complained of a sense of tension or bursting, but no pain. We then ceased throwing air into the bladder, allowing what was in already to remain, keeping up as it did a steady, equal, well-directed pressure on the tumour. After the expiration of five minutes, we threw more air into the bladder, when the patient exclaimed, slowly, "Oh! now you are forcing something up to my stomach." I retained the bladder some time longer in its situation; and then, previous to withdrawing it, permitting the escape of some air, I introduced my finger, and had the satisfaction of finding that the tumour was no longer in the *pelvis*, and that the *os uteri* lay within reach of my finger, pointing downwards and backwards. * * * The retroversion having been rectified, I would introduce, as a pessary, a gum elastic bag, constructed on this principle, and inflate it to a proper state of distension." (p. 76.)

1315. If the fitness of these different modes of treatment be compared, the preference must, from the result of experience, be given over all other to the replacement through the *vagina*, as a far greater number of successful cases to have been ascribed it than to that by the *rectum*, which has been often unsuccessfully attempted, even with the whole hand, and with the employment of great force (*k*). As to the more heroic proposals for realizing the replacement, none indeed, except puncture of the bladder, is permissible, as in the cases where, after emptying the *rectum* and bladder, the symptoms are not diminished, and the proposed manipulation is insufficient, such fixing of the womb in its unnatural position may occur, that the replacement is impossible in any way, as **Hunter** found on dissection of a person who died from this disease (*l*).

1316. In reference to retroversion of the womb in women not pregnant, those rules apply, which have been given for the removal of the symptoms caused by the retention of urine and stools. As to the replacement,

Schweighaeuser considers it unnecessary, in which opinion **Schmitt** also concurs, as by emptying the bladder with the catheter, and the intestinal canal with opening clysters, and the previous use of neutral salts, with carefully observed position on the side, the rump being raised, and the upper part of the body bent down, nearly always the effect is produced, and the womb gradually resumes its natural position, whilst also the swelling gradually subsides. This may be assisted, if with two fingers introduced daily into the *vagina*, the base of the womb be raised gradually but carefully. If the symptoms be inflammatory, merely mild remedies, emulsions of linseed or almond oil, fresh castor oil, luke-warm bathing, steaming, by means of a sponge laid on the generative organs, relaxing poultices upon the belly, and even general and local blood-letting, and copiously rubbing in mercurial ointment on the insides of the thighs. When the most pressing symptoms have been removed or lessened, then the replacement is to be especially attended to. Only when retroversion of the womb exists without any appearance of acute inflammation, may the replacement be at once attempted, but it must not be too long continued. As to the manipulation of the replacement, all that has been said heretofore applies.

1317. When the womb is returned to its place, it has rarely a disposition to be displaced anew, and the continued position on the side, is sufficient to prevent it. And besides as the womb enlarges during pregnancy, its retroversion is no longer possible. If there be a special disposition to retroversion, a round or oval pessary, with a pretty large aperture, or a sufficiently large piece of sponge introduced into the *vagina* and fastened with a T bandage, will prevent it. This applies also after the replacement of the unimpregnated womb. The patient should very carefully avoid keeping on her back (*a*).

["In some few instances," says **Rigby**, "the displacement has been permanently removed by once rectifying the position of the *uterus* with the uterine sound; but this favourable result is rather the exception than the rule, and some mechanical means is therefore required to retain the *uterus in situ*. The supporter used by Professor **Simpson** is excellently adapted to this object, and has answered well It consists of a pin the length of the uterine cavity, (two and a-half inches,) fixed in a disc or button on which the *os uteri* can rest, connected with, and kept in proper position by a little frame resting on the *mons Veneris*, which is fixed and properly adjusted by tapes. Another and equally ingenious mode of supporting the *uterus* he has obtained by means of a species of pessary, to which he has fixed the pin by a spring hinge, like that of a knife-blade. I have never tried this last, but to the other I can bear most favourable testimony, having applied it in a considerable number of cases with which I propose to illustrate this subject. I have lately altered the form of the pin which is passed into the *uterus*, making it flat, instead of round, and broader, so as to adapt it more exactly to the shape of the cavity. The pressure which it exerts on the internal surface of the *uterus* is thus more equable, and over a larger space, and consequently does not produce so much irritation, which, especially at the catamenial periods, is occasionally troublesome, producing also a profuse discharge, and for a longer period than usual. To obviate the chemical action which takes place in an instrument made of German silver, I have had this portion of it made of ivory, at the suggestion of my friend Professor **Retzius**, of Stockholm, to whom I shewed it, and in two cases it has been worn with much more comfort than with the ordinary pin; the objection, however, to the chemical action on the uterine secretion upon the German silver Professor **Simpson** had already remedied by eloctrotyping it with gold.

"The length of time during which these instruments require to be worn varies a good deal, and I have reason to believe that in cases where the displacement has returned, it has been owing to my having removed the support too soon. I believe that a month

---

(*a*) **Hunter, William**; in Medical Observations and Enquiries, vol. iv.

is the minimum period, and that in most instances our chances of success will be much greater if the period be extended to two months, or even longer. (pp. 125, 26.)]

1318. The *Antroversion of the Womb* is more rare than its retroversion, and occurs in both the impregnated and unimpregnated state (1). In the former case it is consequent on violent exertion, on vomiting, on a false step, and so on, with violent pain in the region of the stomach and belly, febrile symptoms, and frequent urgency to void the urine. The region of the stomach is somewhat tender on pressure, the whole belly, full, puffed up, especially the hypogastric region. The stress upon the *pubes* is very troublesome; the forcing of the urine very painful; in which, however, but little is discharged, and only in drops; therewith usually is there great urgency to going to stool, with thin and small motions. A swelling as big as the fist, seems to lie in the depth, behind the pubic *symphysis*; it can, however, only slightly be felt. The drag upon the bladder becomes exceedingly severe, without a drop of urine being discharged, a violent attack of fever takes place, disposition to vomiting, and the hypogastric region will not bear the least touch; the distended urinary bladder may so cover the swelling of the womb that it can no longer be felt. On examining the *vagina*, its entrance is narrow; the finger more deeply introduced, strikes immediately behind the pubic *symphysis*, upon a semilobular swelling, which drops into the little *pelvis*, feels smooth, elastic, and soft, and somewhat tender. The vaginal part is either not at all felt, or only with difficulty, in the more free hinder space of the *pelvis* above, pressed against the *rectum* in the hollow of the rump-bone, and otherwise forming a continuation with the swelling, so that the finger cannot be carried round between the two. Neither the vaginal portion nor the swelling are movable by pressure.

The symptoms of antroversion of the impregnated womb differ according to their degree, the period of its origin, and the sensibility of the patient. In the above-described way has HACHMANN (*a*) noted it in antroversion, occurring suddenly in the third month of pregnancy, from a false step. BAUDELOCQUE (*b*) mentions a case of antroversion in the second month of pregnancy after an emetic. NOLDE (*c*).

[(1) BLUNDELL seems to think antroversion of the womb scarcely to be a diseased condition. "It is said," he observes, "that sometimes a change of position may take place, in which the *fundus* comes forward, and the mouth recedes, and which altered position writers have denominated *antroversion* of the *uterus*: but the truth is, that the womb is almost anteverted, frequently the *fundus* is pushed down below the *symphysis pubis*. Repeatedly, in making examinations, have I perceived it in this position, between my fingers, so that, in my opinion, these anteversions of the *uterus* can scarcely be looked upon as extraordinary and morbid. I might say, with truth, that they are perfectly healthy." (p. 21.)

JOHN BURNS (*d*) says:—"Of this accident I have never seen an instance during gestation, and from the nature of the case, it must be very rare; but I have met with it, from enlargement of the *fundus uteri*, in the unimpregnated state." (p. 260.) BOIVIN and DUGÈS say they have had frequent occasion of observing, after parturition, a decided inclination of the *fundus uteri* forward, the condition of the womb being intermediate between obliquity and retroversion.

This form of displaced womb is mentioned also by GRAY, of New York (*e*), as "a dislocation of the womb downward, and slightly backward, the *os tincæ* tending towards the *coccyx*. The ano-perinæal region of VELPEAU, or the *perinæum posticum* of the older anatomists, from relaxation of the *levator* and *sphincter ani*, becomes enlarged, and the triangular space between the point of the *coccyx* and the tuberosities of the ischian bones, forms, in consequence, a broad deep *cul-de-sac*, into which the *uterus* sinks in the line of its own axis, and rests against the *anus* and *rectum*. This posterior dislocation of

(*d*) Principles of Midwifery.

(*e*) On External Pressure in Prolapsus Uteri; in London Med. Gaz., vol. i. New Series, 1838–9.

the womb often takes place in pregnancy, particularly during the first four months; but it also takes place under other circumstances, I have no doubt, and that much more frequently than is commonly supposed. * * * The posterior displacement will be readily recognised by examination *per anum*. The finger will have to pass very much more backward than usual to get around the *os tincæ*, which lies hard against the *rectum*, just above the *sphincter ani*, and is very perceptible to the feel of the Surgeon. In passing the finger *per vaginam*, the neck of the womb is first encountered, occupying the situation of the *os uteri*. The *os uteri* is found lying against the *rectum*, its aspect being backward and downward toward the point of the *os coccygis*, will have to be carried back in a curved form to reach it. The space between the *os uteri* and the posterior termination of the *vagina* appears much larger than natural." (pp. 221, 22.)]

1319. In *treating* antroversion of the pregnant womb, if the swelling be firm and immovable, blood-letting, clysters (of an infusion of *belladonna*, according to HACHMANN) should be first employed, and the urine drawn off with the catheter. If the swelling be thereby rendered more movable, or if it be movable from the beginning, and unconnected with any particular symptoms, its replacement is to be attempted. The patient must be placed on her back, with the *pelvis* properly raised, the four fingers of the right hand being passed into the *vagina* are carried up to the deepest lying part of the swelling, and this is to be forced by a gradually increased pressure upwards, and in its slow yielding, somewhat backwards, whilst the left hand fixes the hypogastric region immediately above the pubic *symphysis*. In HACHMANN's case, very considerable, and for the patient, extremely painful force was employed, in order to lift the swelling out of the little *pelvis*. When this was effected, and the mouth of the womb removed from the rump-bone into the axis of the *pelvis*, the hand was withdrawn, and the pain ceased as by enchantment. Continuance on the back for some time is sufficient to prevent the recurrence of the displacement.

[BOIVIN and DUGÈS mention a case in which the *fundus uteri* inclined forward, lower down than the *cervix*, and in which reduction seemed impracticable; yet, nature alone, during the progress of gestation, accomplished the cure.

GODEFREY, of Rennes, relates (*a*) two instances in which the natural position of the womb was restored simply by position. The first case he was unable to see; but directed that the woman should be put on the side of the bed, with her head and hands on the floor, and with the front of the thighs and legs only resting on the bed. In this position, he says, that the intestines, being drawn towards the diaphragm, the *pelvis* is emptied, and the womb, being no longer pressed on, resumes its natural position. After the patient had been in this posture fifteen minutes, all pain ceased. In the second case the woman was thirty-three years of age, had been pregnant between three and a-half and four months of her first child. She was attacked with weight in the *pelvis*, and frequent disposition to make water. Nothing having been done, excepting that she went to bed, and the symptoms continuing next day, an examination was made, and the neck of the womb was felt behind, and towards the curve of the *sacrum*, while the *fundus* was in front, and behind the *os pubis*, the bladder not being very full, the catheter was not passed, but she was placed in the position just mentioned, upon the side of the bed, for twenty minutes. The feeling of weight in the *pelvis* diminished, and the desire to void the urine ceased.]

1320. The antroversion of the womb in its unimpregnated state, occurs either suddenly or slowly. In the former case, it produces violent pain, fever, great difficulty in voiding the urine and stools; in the latter, the difficulty of passing the urine and stools is less. The patient has, when she walks, the sensation as if a hard body fell upon the bladder, causing urgency to void the urine, which body again falls back when the patient lies on her back. Thence the possibility of confounding this condition

---

(*a*) Annales d'Obstétrique des Maladies des Femmes et des Enfans, Jan. 1842; and London and Edinburgh Monthly Journal of Medical Science, vol. for 1842, p. 313.

with that of a stone in the bladder (*a*). Oftentimes there arise hæmorrhoidal affections, severe pain in the belly, suppressed or too frequent menstruation, and the whites; conception may be prevented. In examination with the fingers through the *vagina*, the base of the womb is found in front above the share-bones, its mouth situated opposite the rump-bone, and frequently so high that it can scarcely be reached. SIEBOLD (*b*) has found the vaginal part connected with the *rectum*.

1321. The *causes* of antroversion of the womb are much inclined *pelvis*, loose connexion of the womb with the bladder, high position of DOUGLAS'S folds, too early getting up after delivery, continual costiveness, organic changes in the base of the womb, and bodily exertion of various kinds.

1322. The restoration of the natural position of the womb is easy. With two fingers introduced into the *vagina*, it is to be attempted to bring down the mouth of the womb, whilst with the other hand above the share-bones, the base of the womb is to be pressed backwards and upwards. The patient must continue a long while upon her back, a bandage should be applied round the belly, close above the *pubes*, and if this be insufficient to keep the womb in its place, it must be supported with a ring pessary. If the vaginal portion be adherent, it may be divided with the knife, and its reunion prevented, by a sponge put in it for a long while (*c*).

[" The pessary in this case," says GRAY, "does no good whatever; it is thrust into the ano-perinæal region, already rendered a sac by relaxation, and by the presence of the dislodged womb, and there, as a really foreign body, excites the same sensation, and keeps up the same irritation and discharges which the womb had done, and generally, as may readily be supposed, the latter are of a very aggravated character; whereas the new instrument of Dr. HULL, (his utero-abdominal supporter,) by pressing the ano-perinæal region upward and inward, directly opposes the descent of the womb, and, at the same time, diminishes the capacity of this region, whilst the hypogastric support of the apparatus prevents the descent of the abdominal *viscera* into the pelvis." (p. 222.)]

E.—OF CURVATURES.

1323. *Curvatures* (*Curvaturæ*, Lat; *Verkrümmungen*, Germ.; *Courbures*, Fr.) are remarkable deviations of certain parts of our body from their natural direction, depending either on an actual bending in the continuity of the bones, or on their bending and distortion in the neighbouring parts, that is, in the joints.

1324. Curvatures are either vices of the primary formation and congenital; or they arise later, and are ordinarily developed without pain. The bones are not divided as in fracture, nor completely displaced at their joints as in dislocation. Only in a great degree of curvature, if the joints be also distorted, deviations gradually occur in the joint-surfaces of the displaced bones; just as in long continuance of the ailment, single bones are differently changed in their form, diminished by absorption, or united by *callus*.

1325. The erect posture of our body, and of the several organs, depends on the *equal antagonizing operation of the muscles*, and on the *firmness of the bones*. The causes of their curvature are therefore *disturbed abolished antagonism of the muscles*, or *changes in the structure of the bones, whereby they lose their proper degree of firmness*.

(*a*) Journal de Médecine, vol. xi. p. 269.

(*b*) Handbuch zur Erkenntniss und Heilung der Frauenzimmerkrankheiten. Second Edit. Frankfurt, 1821, vol. i. p. 737.

(*c*) KYLL, Beobachtungen über Antroversio Uteri in nichtschwangeren Zustande; in VON SIEBOLD'S Journal, vol. xvii. pt. i.

1326. The antagonism of muscles is disturbed when either one part possesses an absolute excess of activity above the other, or when one part is so weakened, that it opposes no obstacle to the natural activity of the other. This may be effected by palsy, wounds, weakness of the muscles, continued rest of certain muscles, tonic spasm, ordinary exertion of certain parts, especially in particular positions, by which they are wearied, especially in children still under development, by diseased changes in the muscles, as from gout, rheumatism, inflammation, ulceration, ossification, and so on. The activity of the flexor muscles naturally, especially in the *fœtus*, exceeds that of the extensors; hence also the greater number of congenital and original curvatures arise in the course of the flexors.

1327. The muscles which produce the curvature, suffer always a more or less considerable degree of contraction and shortening, so that they are capable only of little extension, or of none at all. In long continuance of this condition, various changes occur in the tissue of the muscles, they lose their fulness, become thinner, even cord-like, and at last are converted into a fibro-cellular, or fatty mass (1). Whatever be the causes which have produced the contraction of the muscles, these changes are always the same, and their common origin lies in the *continual rest*, in which such muscles are found. Muscles, and, through them, their tendons and *aponeuroses*, must be kept in their constant and proper motion and activity if their vitality and organization is to remain natural, and a harmonious relation to exist between the voluntary influence which depends on the brain and the irritability which originates in the spinal marrow. If the activity of a muscle be damaged by one of the above-mentioned causes, and the muscle be kept in constant rest, it gradually diminishes, and at last all voluntary influence over it is lost, and its irritability and tone increase correspondently; by longer continuance of this condition, the tissue shrivels up, becomes unyielding, is to a certain degree atrophied, according to the same law that the intestine below an artificial *anus*, or a vessel which no longer contains blood, shrivels up, grows together, and at last wastes away. The rest of a muscle, when its contraction has once taken place, is therefore continual, because all voluntary motions which the patient attempts with the curved part, can occur only in such one way and direction, that thereby no outstretching and extension, but only a greater shortening of the contracted muscles, can be effected. A close observation of the motions in curvatures, especially in the feet, shows this remarkably. It is clear, that under such circumstances, the nervous influence and nourishment must be diminished in the muscles, and the diminution of the nervous influence may increase up to actual palsy, although the contraction of the muscle continue. In this way also is explained the reason why in palsy, which originates from the brain, and loss or diminution of the voluntary influence depending on the muscles, the muscles are contracted, whilst in palsy, proceeding from the spinal marrow, they are lax and atonic. Spasm, produced by topical causes in the muscle itself, or by reflected activity of the spinal marrow, may be the first origin of contraction of the muscles, and of the curvature thereon depending; but the continued contraction of the muscle is not to be considered as a consequence of *continual* spasm, but of the sustained rest of the muscle, and its diminished voluntary action. The same is observed in inflammation, and in all painful affections when certain muscles are kept in a continued quiet state. The most direct proof of this opinion is given by the bearings of the limb, if its natural direction be restored, in which case the recapability of motion, and the voluntary influence again gradually returns, and in the same measure, the nutrition of the muscles is increased, and their bulk enlarged, as I have especially observed, after the cure of curvatures by cutting the tendons.

(1) Guérin (*a*), who, in all contractions assumes a convulsive retraction of the muscles derived from the brain, whence ensues an indisposition to the growth of the skeleton, change of bulk and fibrous degeneration disturbed functions, supposes that muscles, which by other causes have been relaxed and shortened, do not exhibit the hardness and fibrous degeneration, as the former contract, but these are disposed to fatty degeneration.

1328. The natural connexion of bones may be disturbed by rickets, *osteomalacy*, scrofula, venereal, cachectic diseases, inflammation, suppuration, and so on. The softened bones are then exposed to the action of the muscles, and drawn according to the direction of the force acting upon them; or the weight of the body is sufficient to curve them; from which latter cause such curvings most frequently happen in the trunk and the bones of the lower extremities.

Frequently do the just-described causes occur at the same time, and in inverse proportions; the curvings, however, most commonly arise out of unnatural activity of the muscles.

1329. As to the *prognosis* of curvatures, all depends on their extent and how long the curvature has existed, and in how far the causes originating them may be got rid of. The younger the subject, and the less the curvature, so much the more favourable is the *prognosis*. In older subjects, and long-continued curvature, the treatment is always protracted, and in many cases, often only an aggravation of the disease can be prevented. When in curvatures at the joints, organic changes of the bones, destruction, *anchylosis*, and so on exist, the disease is incurable. Curvatures depending on muscular contraction, generally allow a better *prognosis* than those from diminished connexion of the bones. But if the muscles have become so wasted by long-continued curvature that their lengthening can be of no use, which is however difficult to determine, they are incurable.

1330. The *cure* of curvatures depends on the removal of the causes, and the restoration of the natural direction of the curved parts. When the firmness of the bone is altered, such remedies must be employed as therapeutics have pointed out as fitting to the special diseases which cause the changed coherence of bones, together with the simultaneous employment of suitable contrivances and apparatus by which the straight direction may be restored. Mere mechanical treatment is entirely useless if the diseased state of the bony system be not removed.

1331. If the origin of the curvature depend on the disturbed equilibrium of the muscular activity, the treatment must be directed according to the different causes. Usually rubbing suppling remedies into the shortened and contracted muscles, and spirituous rubbings into the stretched and lengthened muscles are recommended; but from these remedies there is really less benefit than from the motion and extension of the contracted muscles which arises from their application. As with long-continued curving, the nervous influence is diminished in the contracted and shortened muscles, and a lessened activity of the nerves of

---

(*a*) Gazette Médicale, April, 1838. No. 14.

motion is accompanied with a certain degree of curvature and wasting, so may sharp irritants, vesicatories, and even moxas, act beneficially in quickening and increasing the vitality, which remedies are especially indicated in actual palsy. In reference to this object, kneading, rubbing, and stretching the muscles, are very serviceable; but above all, suitable *gymnastics*, (with careful regard to the somewhat necessary improvement of the general state of health,) as first introduced by DELPECH (*a*). Slighter degrees of curvature may be got rid of by these remedies alone; but if the curvature be greater, they must be accompanied with the application of suitable machines and apparatus.

1332. If with long-continued curvature from shortening of the muscles, such change of their tissue have been produced, that by the treatment proposed it can be removed either with extreme difficulty, or not at all, the subcutaneous cutting through the shortened muscles, or their tendons and *aponeuroses*, (*myotomia*, *tenotomia*,) if possible, is the most proper remedy. Between the two ends of the divided tendon which retract, the upper more strongly than the lower, blood is effused, which coagulates and unites with the whole internal surface of the wound, and especially with the ends of the tendon. Exudations of plastic lymph soon occur, particularly from the ends of the tendon, presenting whitish thread-like streaks, running from one to the other, and gradually form a mass resembling fibrous tissue, which is capable of due extension, and sufficiently strong to answer the function of the muscles. This operation is therefore especially indicated under the above-mentioned conditions, if there do not at the same time exist such considerable changes in the bones, and from the long continuance of the disease, such a degree of wasting in the muscles, and the whole limb, that by the mere lengthening of the muscles, the restoration of their natural position cannot be effected, which however it is often difficult previously to determine, and when the causes giving rise to the contraction, gout for instance, still exist. The various objections made to this operation, the repeated shortening of the tendons by the gradual contraction of the newly formed intersubstance, as observed in every scar, as well as the injury to the natural direction and motions of the part from excessive activity of the antagonizing muscles, are without foundation, and contradicted by the large experience of modern times. The pain and wound are in this operation usually slight, and no particular symptoms occur. If in rare cases such be observed, as violent inflammation, with destruction of the cellular tissue, exfoliation of tendons, and so on, they must be ascribed rather to the peculiar relations of the constitution of the patient, or to the proceedings in the operation and the after-treatment, than to the operation itself. The straightening of the part, and the stretching of the tendons by proper apparatus, is most properly commenced some days after they have been cut through, when the external wound is healed, to which time a light bandage covering the part keeps it in a proper position. The employment of extension immediately after the division is improper, as thereby the two ends of the tendon are too far separated, and bad symptoms may be brought on. Too late use of extension when the intermediate substance has a trained firmness, renders the lengthening difficult, and even impossible.

The division of shortened muscles and tendons, early employed on the *m. sterno-*

(*a*) De l'Orthomorphie par rapport à l'espèce humaine, &c. 1828. Paris and Montpellier, 2 vols. 8vo. atlas, 4to.

cleido mastoideus in wry neck, (Roonhuysen, Meeckren, Ten Haaf, and others,) and then forgotten; again revived by Sharp, by Tilesius, and Sartorius, upon the Achilles' tendon in club-foot, by Michaelis extended to other tendons also, were subsequently little thought of, and only employed in certain cases of contraction, by Dupuytren and Dieffenbach in wry neck, and by Delpech employed in horse-foot as a *subcutaneous* division. But more recently, it has been first brought into practice as a subcutaneous division by the large experience and observation of Stromeyer; and by Dieffenbach, Stöss, Duval, Scoutetten, Bouvier, Pauli, myself, and many others has it been variously practised and extended to different muscles, as more attention has been paid to the special treatment of curvatures. The mode of cure of tendons thus divided, Delpech formerly, and in modern times more especially, von Ammon (*a*), Duval, Bouvier, and others (*b*), have explained by experiments on brutes.

1333. *Wry Neck* consists in such distortion of the neck, that the head is inclined forwards, aside, downwards, frequently even to the shoulder; and the face turned more or less to the opposite side, and at the same time forwards and upwards; the chin raised proportionally higher, as the head is in a greater degree drawn down. The patient can, under these circumstances, move the head either not at all, or only in a slight degree; often can it be done only by the assistance of another, and frequently it is not in any way possible. This disease may originate in an irregular activity of the muscles of the neck, especially of the *m. sterno-mastoideus,* in a large unsightly scar, or in a distortion of the neck itself. When long continued, there is always dissimilarity in the two sides of the face.

Distortion of the neck, as consequent on inflammation and suppuration of the joint-surfaces of the *vertebræ* of the neck, has been already considered (*par.* 263.)

1334. The most frequent *cause* of wry neck is unnatural muscular activity. It is either congenital and depends on irregular position of the child in the womb (1); or it arises from violence during delivery, which affects the *m. sterno-mastoideus* (2); or it comes on later from the habit always hanging the head to one side, especially in children, if they be constantly carried on one arm; if, on account of the continuance of any

---

pain in the neck it be inclined to one side (3), by spasm and organic change in the structure of the *m. sterno-mastoideus.* If the cause lie in the unnatural activity of this muscle, it is always found, on the side to which the head is drawn, stretched like a cord, hard and unyielding; in attempting to bring the head into its proper position, the muscle becomes more tense and prevents it (4). It is really only the *m. sterno-mastoideus* which is primarily shortened, and most commonly on the right side; rarely, also, the *m. cleido-mastoideus* and *cucullus;* the *m. platysma myoides,* may also be shortened. Frequently is the *m. sterno-mastoideus* of one side palsied, and the natural contraction of that of the other draws down the head. In this case the dissimilarity of the two sides of the face and the distortion of the features are not so great, as in wry neck from unnatural muscular contraction; the head is drawn only towards the shoulder, but the chin is not raised (5). That the cause of the evil is in the bones is known, when no change can be observed in the muscles, and the general symptoms of softening of bone be present. The head is also usually more movable than in the former cases (6).

(1) STROMEYER (*a*) remarks on the coincidence of congenital shortening of the *m. sterno-mastoideus* with the irregular position of the child, so that a breech-birth takes place, or turning is necessary.

(2) After difficult delivery, and after the application of forceps, a little round bluish doughy swelling above the collar-bone, corresponding to the course of the *m. sterno-mastoideus,* is frequently observed, which, after subsiding, leaves to be felt a hard thick substance, depending on partial or complete tearing of the muscle (STROMEYER, DIEFFENBACH.)

(3) I have noticed a wry neck which arose from the application of a blister behind the ear, and in a short time became considerable.

[(4) Although generally in wry neck the muscle or muscles causing it are felt contracted like a cord, yet this is not always so. SYME (*b*) mentions an instance of this kind in a boy with lateral curvature. "Observing that his head inclined to one side, I examined the sterno-mastoid, and found it, not tense and rigid as I had expected, but soft and yielding. I perceived, however, that when an attempt was made to raise the head, the muscle resisted and became tense, and therefore concluded that it was the seat of the evil." (p. 273.)

(5) BRODIE mentions (*c*) a remarkable example of wry neck alternating with insanity, among the instances he gives of persons "labouring under some disease in the brain, in whom a particular symptom, referred, perhaps, to a distant part of the body, is so severe, or so distressing, that they regard it as the original disease. * * * In many of these cases, the cause of irritation seems to operate always on the same part of the *sensorium,* and there is little or no variety in the local indications by which it is rendered manifest. At other times it has no determined seat: it may affect at first one portion of the brain to which a certain function belongs, and then it may affect another portion, whose function is entirely different, and the symptoms vary accordingly. * * * A lady became affected with a spasmodic affection of the sterno-cleido mastoid muscle, producing what is commonly called a spasmodic wry neck. This symptom continued unabated for a year, and then suddenly left her; but as the spasm in the muscle ceased, she fell into a state of mental depression, amounting to insanity; and in this she continued during the whole of the second year. At the end of this period she recovered of the disordered condition of her mind, and the spasm of the muscle returned, continuing from that period up to the time of my being consulted three or four years afterwards." (pp. 7, 8.)

(6) SYME remarks:—"It may be well to warn against mistaking for wry neck depending upon muscular contraction, the distorted position of the head which proceeds from *caries* between the *occiput* and *atlas.* The latter disease, like the former, usually occurs in young persons, presents to a careless observer similar symptoms, and if

(*c*) Lectures illustrative of certian Local Nervous Affections. London, 1837. 8vo.

confounded with it, leads to treatment not only useless, but extremely dangerous. (p. 273.)]

1335. The *prognosis* in wry neck depends especially on the cause and duration of the ailment. In young persons, if the cause be in the muscles, the *prognosis* is always favourable; and this applies also, under similar conditions, from curvature of the bones. But, if by long continuance of the ailment, the *vertebræ* of the neck have undergone a change of form, or have become united by adhesion, which may be ascertained by careful examination with the fingers, and simultaneous movement of the neck, the ailment is incurable.

1336. The *cure* of wry neck varies according to its causes. If dependent on unnatural activity of the muscles, it must be attempted to relax the contracted *m. sterno-mastoideus*, by rubbing in suppling remedies, as well as by exciting contraction of the relaxed muscles on the other side by volatile, strengthening rubbings of aromatic spirit, arrack, rum, and the like, and even by the employment of electricity or galvanism. After rubbing, attempts must be made to stretch the shortened *m. sterno-mastoideus*, and at the same time, to bring the head straight, which manipulation must be continued for a quarter or half an hour, during the day, till the head have been brought to its natural place, and even bend somewhat to the opposite side. The patient must also be permitted frequently to turn his head aside.

For the purpose of keeping the head straight, various apparatus and machines have been proposed, for instance, that of LE VACHER, with alteration by DELACROIX (*a*), KOHLER's cap, and others. JÖRG's (*b*), apparatus, however, seems to answer the purpose best; it consists of a head-band and stays, on the front of which is attached a spring, from whence a strap carried round the neck and fastened behind the ears in the region of the mastoid process, is fastened to the head-band. This apparatus may be worn day and night, and the manipulation may be also continued. As the head, though thereby straightened, is still however held somewhat forward, towards the end of the cure the band must be carried beneath the arm of the ailing side, go up through a ring, and be fastened at the place mentioned. The apparatus must be worn (latterly only for some hours in the day) till the antagonism between the two sterno-mastoids is perfectly restored. DELPECH (*c*) recommends a stretching apparatus, when in bed, and drawing the head by means of a loop fastened to the head and to the side of the bed.

1337. But if, when the disease have already existed for some time in a certain state, this treatment have no result, it is extremely irksome and tedious; the division of the *m. sterno-mastoideus* then leads more speedily to the object, and is, indeed especially, the only cure in all cases where, by the continuance of the ailment, organic changes occur in the structure of the *m. sterno-mastoideus*, which render all lengthening by the proposed treatment impossible. The reasons which have been brought against this operation, rejected unconditionally by JÖRG, are quite untenable; the operation is free from danger, accompanied with little pain, and the result is quick, even after the disease has existed twelve or sixteen years, or even longer.

(*a*) GERDY, P. N., Traité des Bandages et Appareils de Pansement. Paris, 1826. 8vo. et atlas 4to.—VON FRORIEP's Kupfertafeln, pl. clxix.

(*b*) Above cited, pl. ii.

(*c*) Orthomorphie, vol. ii. p. 209.

Roonhuysen (*a*) and Ten Haaf (*b*) cut through the *m. sterno-mastoideus* from without inwards, with a fold of the skin raised. Von Meeckren (*c*) effected the division with a pair of scissors; Minnius (*d*) first destroyed the skin over the muscle with caustic, and then cut it through with scissors. Sharp (*e*) made a transverse cut through the skin, and divided the muscle from within outwards with a knife introduced behind it. This treatment was recommended by all the later writers, till Dupuytren and Dieffenbach (*f*) proposed the subcutaneous division of the muscle, in which manner the operation has been performed with the most successful results, by many Surgeons and by myself.

1338. The subcutaneous division of the *m. sterno-mastoideus* is performed in the following manner. The patient sitting on a stool, one assistant draws the head to the opposite side, and another pulls down the shoulder of the ailing side, in consequence of which the muscle projects strongly at its shortest part. The skin above it is then taken hold of with the thumb and forefinger of the left hand, well drawn away from the parts beneath, and a *narrow, slightly convex, straight knife*, held flat, is to be thrust an inch or two above its lower insertion, through the skin, and carried close behind the muscle, to the other side beneath the skin, but without piercing the latter. The edge is then turned towards the muscle, and the thumb of the left hand being placed on the muscle, to fix it against the edge, the muscle is divided, without cutting the skin, in drawing out the knife. At the commencement of the division of the muscle, a dull and sometimes tolerably loud crack is heard, upon which the head is often immediately drawn straight by the contraction of the *m. sterno-mastoideus* on the other side; but sometimes the old position is retained, and even more strongly. At the moment when the knife is drawn back, if pressure be made with the thumb upon the part divided, and no blood be poured out beneath the skin, a firm compress of lint is to be applied, and fastened with sticking plaster, and a bandage carried obliquely over the neck and breast. Two cloths carried round are sufficient to support the head; they do not, however, keep it straight, but leave it in its early oblique position.

The choice of place for dividing the *m. sterno-mastoideus* (fixed by Latta at half an inch, and by Dieffenbach at two inches above its insertion) is indifferent, and must be guided by where the muscle can be isolated safely; however, the deep division at the tendinous part is more preferable, because it is liable to less reaction than the division of the muscle.

I use a straight, narrow, *slightly* convex knife, because it acts more surely and correctly than a knife with a concave edge; and, like Dieffenbach, I make only one thrust, in which he uses a narrow sickle-shaped knife, much curved at its point. Stromeyer, who has frequently performed the division of the *m. sterno-mastoideus* from before backwards, employs for the purpose a narrow curved knife, with its convexity cutting, which he thrusts through a fold in the skin, an inch broad above the collarbone, and by the entrance of the knife divides the muscle. For those cases where the muscle cannot be sufficiently isolated, he has proposed a peculiar forceps-like instrument (*g*).

1339. Ordinarily the division of the *m. sterno-mastoideus* is sufficient; but if the *m. cleido-mastoideus*, or a *cleido-mastoideus secundus*, (Stromeyer,) or the clavicular portion of the *m. cucullaris* be shortened, the

(*g*) Above cited, pl. viii. f. 1, 2.

division must be effected with a straight or convex narrow bistoury, or with **Stromeyer**'s instrument, according to the rules given above.

1340. If the patient be kept quiet, in the horizontal posture in bed, and on antiphlogistic diet, generally no further symptoms occur. After some days the external wound is healed. The muscle, at the place of its division, usually presents a slight swelling; frequently also a slight fluctuation of blood is felt, in which case, according to **Dieffenbach**, sticking plaster should be applied anew somewhat tighter, in order to promote its absorption, which is usually effected in a few days. Applications of warm lead wash, and rubbing in warm oil to get rid of the last tension, are generally superfluous. If *pus* be formed, it must be discharged by a puncture, and the wound treated simply. A pasteboard cravat of half the usual height, folded in a cloth, and applied on the side of the division is, according to **Dieffenbach**, more serviceable in preserving the straight posture of the head than all violent extension, on which point I, from experience, entirely agree with him.

Stromeyer (*a*) considers that only by a stretching apparatus (pl. vii.) are we in a position to obtain all the advantages of the operation which can be attained, because only in the horizontal posture can the muscles of the neck be completely extended, and it is only possible to stretch the head towards the diseased side for the purpose of giving the *m. sterno-mastoideus* its whole length, and enabling it again to extend itself. He therefore puts it as a question whether, in very bad cases, it be not advisable to begin the extension directly after the operation, in order to avoid a repetition of the division.

If after perfect replacement, the freest motion of the neck be again given, and complete similarity of the sides of the face obtained, yet is it observed in some cases, that at the moment when the muscular system is not in action, the head is somewhat disposed towards the ailing side, manifestly because there the *turgor vitalis* is less. **Stromeyer** does not know whether this be entirely lost in age. Spirituous rubbing seems to him to contribute somewhat to the diminution of this relaxation, but above all, the continued use of the stretching apparatus, some time after the subsidence of all resistance.

1341. If the cause of wry neck be spasm of the *m. sterno-cleido mastoideus*, in which case the ailment is always more or less painful, accompanied with radiation of the pain, according to the branchings of the nerves, and often alternating, it must be inquired whether or not any internal cause be in play, against which the treatment should be directed, and antispasmodics employed both internally and externally. But if the contraction have at once become permanent, in general all internal and external treatment is fruitless, and cutting through the muscle is the only means whereby not merely the straight direction of the head is restored, but also the painful and spasmodic affections are removed.

Compare the interesting observations hereto belonging of **Stromeyer** (*b*) and **Amussat** (*c*).

A spasmodic affection of the *m. platysma myoides*, with radiation on the face and ear of the affected side, was perfectly cured by **Gooch** (*d*) by a transverse division of the muscle beneath the jaw, after he had laid it bare with a transverse incision of the skin across its breadth.

1342. If large scars be the cause of wry neck, their mere division is usually of little use, and the evil may thereby be even increased. The whole scar, together with the thickened and adhering cellular tissue must be removed, and where possible the quick union of the edges of the wound brought about. During and after the treatment, the head must be kept in a proper position. With slight superficial scars only, its straight

direction may be often given to the head, by suppling remedies which are to be rubbed in, and by the bandages prescribed.

1343. If the cause of the wry neck be in a bending of the neck-*vertebræ*, and if it be unaccompanied with *anchylosis*, or change of structure, the above-mentioned apparatus must be used for the gradual straightening of the head.

1344. The spinal column may be curved at any one part, and, according to the direction in which this occurs, are distinguished, *first*, the *lateral Curvature (Scoliosis)*; *second*, the *posterior (Humpback*, *Buckel*, Germ.; *Gibbus*, *Cyphosis)*; *third*, the *Anterior Curvature (Lordosis.)* The spine never deviates according to either of its natural directions, but always in an opposite one. At the same time it is therewith more or less twisted, and this again in a contrary direction. It is evident that the intestines contained in the chest and belly, must consequently have their natural position variously altered, and only the successive origins of these curvatures render it comprehensible, how these intestines are often so considerably displaced, without great disturbance of their functions. The curvatures of the spine have no effect on the transverse diameter of the *pelvis*, if unfounded in general disease, especially rickets or *osteomalacy* (*a*).

This opinion, advanced by **Meckel**, and supported by numerous facts, which, in consequence of careful observation, I hold to be correct, has been denied by **Jörg** (*b*) and **Choulart** (*c*) in so far as they assume, without any general disease of the bones, a decided influence of the curvature of the spine upon the form of the *pelvis*, only that in general disease, or, if the curvature have existed from youth, it is more decided. According to their view, as the spinal column has four natural curves, (at the neck convex forwards, at the back convex backwards, at the loins convex forwards, and on the rump-bone convex backwards,) in all cases where the natural curve increases at any one spot, the other natural curves should also be increased; just as, on the contrary, when the curve takes place in the opposite direction, the other parts of the spine also have their natural curve assume a contrary direction; in consequence of which the rump-bone becomes more curved, or more flattened. In lateral curvature the *pelvis* is always narrowed obliquely by the inclination of the rump-bone toward the one or other side. See also on this subject **Rokitansky** (*d*).

1345. The *inclination of the spinal column to one side, (Scoliosis,)* produces at first a different condition of the shoulders, and one becomes higher than the other; the body is disposed towards the side opposite the curvature, the one side of the back is full, the other concave, and more hollow; and upon it, between the last false rib and the hip-bone, is observed a small fold of the tegument, which increases proportionally as the curvature of

(*d*) Beiträge zur Kenntniss der Rückgrathskrümmungen, und der mit denselben zusammentreffenden Abweichungen des Brustkorbes und Beckens; in Oester-Med. Jahrbüchern, vol. xxviii. pt. i. ii.

the spine increases. With such increased inclination toward the side, distortion of the spine also occurs; the spinous processes are twisted toward the side of the inclination. The whole trunk is gradually bent, the ribs follow the distortion of the spine, are flatter on their concave surface, but upon their convex hinder surface are more strongly arched, are very widely separated from each other, and broader, whence a projection backwards is produced. The breast-bone is mostly oblique, and drawn towards the concave side of the curvature. If the curvature be at the upper part of the spine, the position of the shoulder-blades is much changed. Curvatures at the lower part of the spine affect the carriage of the body less than at the upper. Lastly, curvatures are produced in opposite directions, in which case one is, as it were, equalized by the other. In the highest degree the direction of the bones of the *pelvis* is changed, the one hip-bone stands higher than the other, and, under the circumstances mentioned, (*par.* 1344,) the promontory of the rump-bone may project inwards towards the one or other side, and narrow the entrance of the *pelvis*.

The higher position of one shoulder is always present in *scoliosis*, but it occurs alone, and without simultaneous curving of the spinal column, as *high shoulder* (*Humerus elatus.*) Raising up one shoulder, usually the right, by which the elevating muscles of the shoulder-blade become gradually stronger, is the result of bad habit; the lower angle of the blade-bone is raised higher than that of the other side; the hinder edge, however, of the bone remains in the same position, and only after long continuance does the shoulder-blade project especially at its angle. If both shoulders be high, which occurs from bad carriage, as a consequence of corresponding straining of both arms, in bending forwards the head, in short-sighted and old persons, the back is considerably arched, and the head in the same proportion projecting. In a higher degree always, at the same time, some inclination of the spinal column occurs.

[The most common cause of a high shoulder is to be found in the abominable practice of undressing girl's necks, as low as the hanging on of their clothes will permit. Instead of the shoulder-straps of their dress being, as they should be, fairly above the root of the acromial processes, they often, indeed most commonly, either only skirt the extreme end of those processes, and rest on the rounded upper part of the deltoid muscles, or are actually far down on the arms; in consequence of which, the dress having little or no suspension on the shoulders, is constantly dropping, and the girl to save her clothes dropping down, or at least to keep them in place, is continually hitching up the shoulder from which the shoulder-strap most easily slips, and thus the elevating muscles becoming stronger on that side, pull the shoulder permanently up, and produce a very ugly appearance. But the mischief does not stop here, for though there be really no disease in the spine, yet this constant hitching up of the shoulder, causes the head and neck to be thrown to the other side, whilst the chest is drawn out to the same side, and thus a lateral curvature of the spine is produced, and a girl's figure spoiled, for the simple purpose of uncovering her neck and shoulders as far as possible, which, as well for decency, as for the preservation of the child's health, ought to be covered. Many parents have been thus the real cause of their daughter's distortion, if not of more serious consequences; and therefore, in growing girls who have the least disposition to slip their shoulder out of their dress, most especial care should be taken to prevent the possibility of keeping up this habit, by having the dress made so high, that it cannot slip down, and then the sensation of its slipping being lost, the child no longer continues to hitch up her shoulder, and by a little attention to her proper carriage, the mischief, if not of long standing, may be got rid of.—J. F. S.]

1346. The intestines of the chest and belly are variously displaced by the higher degrees of *scoliosis*, in consequence of which the circulation of the blood in the lungs is hindered, difficult respiration, narrow-chestedness, disturbance of the digestion, and so on, arise, which thus explain the usually weakly form of the body in persons affected with such curvatures.

1347. In *Cyphosis* the spinous processes form a convex projection, and the bodies of the spinal column a curve, the concavity of which is forwards, and, as they drop together, the upper approach the lower. At first, the head of the patient inclines forwards; in the supine posture no change is observed, except after very considerable exertion. In the second degree, the inclination of the spine remains, and is always increasing; it projects into a blunt, and subsequently into a sharp angle. If the *cyphosis* be in the *vertebræ* of the neck, breathing and swallowing are especially affected; if the *vertebræ* of the back be curved, the ribs are lengthened forwards, the breast-bone raised, and the transverse diameter of the chest lessened, from which difficulty of breathing ensues. By the dropping of the spine, the bowels are driven down into the *pelvis*, and frequently cause difficulties in digestion. The bodies of the *vertebræ* shrink in a high degree of the disease, and they may be fixed by *anchylosis* in their unnatural position. Inclinations in other directions may, at the same time, accompany *cyphosis*.

Only in the cases where the *cyphosis* depends on *caries* of the *vertebræ* (POTT'S disease) does palsy of the limb occur.

1348. The *inclination forwards* is the most rare of all the curvatures of the spine. The *vertebræ* project forwards in a convex arch, and the spinous processes are thereby approached together in a concave curve. Whence follows, that the *lordosis* can never attain so great an extent as the *cyphosis*, because the spinous processes touch. It occurs always in the *vertebræ* of the loins, and the inconveniences they excite are those of the pendant belly. It has been observed, but very rarely, in the *vertebræ* of the neck.

1349. What has been said upon the ætiology of curvature in general, applies also to that of the spine. There is either a disturbed antagonism of the muscles, or a diminished strength of the bones. The occasional causes which especially favour the various inclinations of the spine are:—

First. In *scoliosis*, careless carriage of the body in various employments, hanging on one side in writing, sitting, especially in the hand-work of ladies, increased exertion of one side, the habit of doing everything with one hand, constantly carrying children on one arm, which acts very prejudicially, as one hip-bone is always more raised and pressed than the other. The younger the patient is, the more prejudicially do the above-mentioned causes operate. If the cause of the curvature depend on unnatural activity of the muscles, they are more firm and contracted on the concave side of the curvature (which, in by far the greatest number of the cases, is the left); if the cause of the curvature depend rather on an altered state of the bones, the difference of the muscles is not so remarkable (1).

Second. In *cyphosis* the cause, for the most part, is in the bones, and the weight of the body itself is sufficient to increase the bending backwards already existing in the *vertebræ* of the back, where the *cyphosis* most commonly occurs; often is there accompanying weakness of all the muscles, which should keep the spine erect, as is frequently the case in children and old persons.

Third. In *lordosis*, in their natural state, the external muscles of the loins are more powerful than the internal; whatever therefore increases the strength of the former, increases also the natural bending inwards of the *vertebræ* of the loins, as long standing with the upper part of the body bent back, great bending back of the upper part of the body in the usual carriage, bearing heavy burdens. *Lordosis* is therefore more frequent in men than in women.

(1) STROMEYER (*a*) supposes that *scoliosis* arises, if not in all, at least in most cases, from one-sided palsy of the inspiratory muscle, viz., the *m. serratus magnus.* The muscle, although still capable of voluntary motions, takes no part in those of breathing, which is especially observable if the motions of the *diaphragm* be restrained by pressure on the belly, and the external muscles of inspiration be excited to increased activity; as then the muscles of the palsied side remain quite quiet. This imperfect palsy is derived from the palsy of BELL's respiratory system, from an incapacity of the affected nerves proceeding from the periphery to reexcite reflected irritation, in which case they still obey the stronger stimulus proceeding from the will. The greater number of cases produced in support of this opinion, permit also another explanation, and, according to what has been already said upon the ætiology of curvatures in general, is this state of palsy of the muscles of inspiration to be considered, not as a primary, but as a secondary state.

According to GUNTHER's (*b*) observations, in snake-like *scoliosis* the muscles neither of the concave or convex side are much wasted, nor are they changed in form, although it so appears as long as they are attached to the body. They are only either stretched where passing over the projections, or folded when lying in the concavities. On the contrary, there appears a decided difference in the strength and weight of the corresponding muscles of the two sides, and that muscle increases which has an unfavourable position, and is therefore required to act with more power. So, for instance, the *m. cucullaris* of the concave side exceeds that of the convex about 90 grs. in a weight of 1550 grs.; the *m. latissimus dorsi* of the convex that of the other side about 120 grs. in 1160 grs. If the relations of one muscle be so disproportionate that, in its natural circumstances, it either act not at all, or irregularly, its circumstances change, so that it detaches itself from some places, attaches itself to others more suitable, or forms new heads.

[According to ZINK's opinion (*c*) *scoliosis* generally commences from the fifth to the eighth year of age, and between the third and fifth dorsal *vertebræ*, and the deviation is almost always towards the right shoulder-blade; that shoulder exhibiting an excess of nutrition over the left, which is especially apparent in the blade-bones themselves. Such children have a remarkable tendency to lean towards the weaker side, while on every occasion requiring muscular exertion, they prefer the stronger hand. "From repeated observations," says ZINK, "I am convinced that the greater part of the mischief here detailed, is effected during sleep, and consequently, is in operation during one-third of the patient's daily existence. The heart then leans down towards the left side, and the lung on that side is compressed, one lung only (the right) performs its full office, and the muscles of respiration on that side are in a state of activity, greatly exceeding that of the left. I have also ascertained that the convexity of the deviation of the spine accords exactly with the insertion of those muscles which are most active in the process of respiration. This deviation from the perpendicular, so high up in the spinal column, is often overlooked, and the inferior and secondary contortion to the left side in the lumbar *vertebræ* is often regarded as the primary affection." And he further observes:—"This disease is more frequent among the wealthy, and more commonly in females than males."

SYME (*d*) observes:—"There is one particular condition of lateral curvature certainly not common; yet, judging from the number of cases that have fallen within my own observation, I should say not extremely rare, in which complete relief may be afforded by the division of a muscle, and in no other way. I allude to spinal curvature depending upon wry neck, caused by contraction of the sterno-mastoid. This muscle is liable to contraction both spasmodic and permanent. The former does not, so far as I have seen, affect the shape of the spine, and in two cases treated by division, did not yield to the operation. But the latter is apt to produce lateral curvature in every degree, and may be remedied with no less ease than certainty by subcutaneous incision." (p. 271).]

1350. The special *diagnosis* of curvatures in regard to their cause, is now to be considered. Great muscular weakness, resulting from previous disease, disturbed digestion, disturbed sexual development, and the like, by which gradually the joints of the spine are left to the unaided and inadequate strength of the ligaments, is characterized by weakness of the muscles, pain, and weariness of the spine, speedy tiring after every move-

(*d*) Above cited.

ient, dropping of the spine to one side or other, or forwards, and great mobility of the spine; so that, on examinination in various positions of the body, alterations appear; when lying down, the deformities disappear, if they be not very great. In children who are very stout, and have a large head, whose muscles are too weak for the weight of their body, and especially of their head, there appears commonly at the time when they should begin to walk, incapability of so doing; and, when sitting, a great dropping forwards of the head, by which the spine projects backwards in a large curve; in lying down, this is diminished, but, with carelessness, it becomes permanent, and always more considerable.

1351. The swelling of the fibrous intercartilage has been considered by Delpech (*a*) as no rare cause of spinal curvature; it proceeds generally from one point to all the *vertebræ* in various degrees, or all may be at once attacked. In the former case sometimes severe, sometimes slight pain occurs at any one part of the spine, which consequently is deformed. This pain has not, however, always a definite and precise place: the patient points out the seat of pain in a vague manner, frequently on one or other side of the body, frequently at the *epigastrium*. A curvature appears, which, at first, is inconsiderable, and forms a pretty large curve. The direction of the inclination is determined by the greater or less thickness which one or several fibro-cartilages have obtained at any one part of their extent. Hence may arise curvatures backwards, forwards, and especially sideways. If a complication exist at the same time, for instance, a too short lower limb, a deforming scar, long-continued pain, a forcibly-continued position, and so on, they may determine the direction of the inclination. This is, at first, slight, indefinite, and even transitory; it subsides, at least partially, in the horizontal posture, in the morning, immediately on getting up, and so long as the principal functions, especially digestion, are carried on satisfactorily. The curvature extends to the neighbouring *vertebræ*. These new curves disappear in the horizontal posture, and when the body is supported on the hands, whilst the primitive curves still exist. Subsequently these successive curvatures become permanent, and no longer subside in the experiments just mentioned. Sometimes walking and standing are rendered difficult by the curvature; the patient resorts to particular attitudes to keep himself upright, and, in a short time, new deformities are observed in the opposite direction, for the purpose of restoring the equilibrium of the body. These new curvatures may also subsequently become permanent. The curvatures form, at least before they are yet very old, more or less open, but regular arches.

If the swelling attack the fibrous inter-cartilages all at once, (cases which have been noticed by Delpech only in lymphatic and weakly persons,) the patient is not capable of standing upright; he always seeks a resting-place, loves repose, is apathetic, but yet restless; he avoids all exercise and all enjoyments of his age; the slightest walking tires him. Generally there appear disturbance of the digestive organs, palpitation of the heart, and oppression of the chest, which, however, are transitory. The patient avoids bending himself in any one direction; and in the most simple, and shortest walks, has frequent falls, accompanied with pain, which ceases as quickly as it came on, and the seat of which the patient cannot accurately determine. If sufficient pressure be made successively on the spinous process of each *vertebra*, violent pain is excited in each, and an

---

(*a*) Orthomorphie, vol. ii. p. 53.

epileptic attack, accompanied with convulsive movements of the upper and lower limbs. If the examination be made whilst the patient stands, epilepsy follows, with the painful sensation produced by pressure. On examining the spinal column, it is easily perceived that a greater or less mobility exists in almost all the *vertebræ*, but especially in those in which the pressure causes the symptoms mentioned. There still, however, appears no permanent deformity; but if the patient be carefully suspended by the head or by the arms, all appearance of deformity subsides, and it is clear that all are possible, but none yet exist which may become permanent. If the ailment continue to permit it, successive and alternate fixed curvatures occur, which quickly increase, but always retain their fundamental character, to wit, a greater or less large arch, generally of pretty large extent, but regular, and free from all angles. These curvatures very readily increase.

1352. In the curvatures of the spinal column from softening of the bones, the spine usually projects backwards where one or several bodies of the *vertebræ* have sunk in, and a vertical flattening of the body of a *vertebra* takes place. The bending backwards is frequently connected with a slight disposition towards the side. At some distance from the original curvature, large curves and almost regular arches are formed. In rickets there are accompanying swellings of the condyles of the tubular bones, which also bend in various parts, disturbance of digestion, distended belly, and so on. In *osteomolacy*, the whole constitution is much affected for a long while before the curvature takes place, severe, commonly wandering pains, spreading over the breast and belly, frequently fixed in the spine, which increase at every movement, even on turning round in bed, precede and accompany curvature; febrile symptoms frequently appear; digestion and all the functions become more and more affected; the weakness is always greater, and partly on that account, partly on account of the pain at every movement, the patient keeps one position in bed, which determines the direction of the inclination of the spine. In these curvatures the ribs especially, and the bones of the *pelvis*, are decidedly changed in their form and direction.

1353. The *prognosis* in curvatures of the spine, is directed generally according to the age of the subject, the duration, the cause, the degree, and complication of the disease. Many curvatures which, as yet, have not become permanent, and are connected with general disturbance of the health and weakness of the muscles, may, indeed, in rare cases subside, form favourable change of the constitution during the period of development, or from accidental improvement of the general state of health; but reliance on this self-assistance of nature is always dangerous; for, in most cases. experience commonly shows the case getting worse. The younger the patient, the slighter the degree of curvature, so much the easier is it of cure; in persons advanced in years, and in adults, the progress of the disease may be arrested by careful treatment, but no perfect cure is effected. If the cause of the curvature be a diseased condition of the bones, the *prognosis* is always more unfavourable than if it were in misproportions of the muscles. If inclinations of the spine, in different directions, exist, the treatment is more difficult than if there were merely one single inclination. In long continued curvatures of the spine, such changes occur in the *vertebræ* that a cure is rendered impossible. It is therefore an important observation, in reference to this point, that the curvature remain without increase some two or three years, and still more important, that for an equally long time, all the vague symptoms of inexplicable injury of functions, which accompany the completion of the deformity, are progressively and completely stopped (*a*). In these cases the curvature is connected with *anchylosis* of the *vertebræ*, and the cure is impossible. In order to ascertain this, the patient, having stripped, should be laid flat on his belly, and rubbed with spirituous remedies on the extended muscles, but with relaxing remedies on those which are contracted, and attempts should be made to restore the spine gradually to its natural direction. If the patient then feel a stretching and stress upon the curved part of the spine, and not at the insertion of the muscles, it may be decided that there is *anchylosis*. This condition of the curvature is more surely indicated, if previous or continued extension of the spine show no change in the curvature. On the other side, if changes in the spine be observed on carefully lifting the body by the head (1), so that the feet do not support the weight of the body, or in extension whilst in the horizontal posture, there is more hope of restoration. *Anchylosis*, however, is not very common, and usually only accompanying a long continued great degree of curvature, and in persons of advanced age. The *scoliosis*, when it first occurs in adults, rarely attains the first degree. The *lordosis* is most easy, the *cyphosis* the most difficult of cure.

[(1) This practice of lifting by the head, to which Chelius very frequently recurs in these diseases, I think very objectionable and dangerous, especially in weakly children, who may be entirely free from disease, as the longitudinal ligaments of the spine may be insufficient to bear the weight of the lower part of the body. Astley Cooper, in his lectures, was accustomed to inveigh bitterly against the foolish trick of showing children the way to London, as it is called, which consists in lifting them up by the chin and back of the head. Chelius's proposal is of the same kind, and equally objectionable.—J. F. S.]

1354. The *treatment* of curvature of the spinal column must be variously conducted, according to the different cause and nature of the deformity, that is, such remedies must be employed as counteract the causes in which it originates, and at the same time, or immediately after the straight direction must be restored by mechanical apparatus and other means operating on the spine. In former times the first indication was almost completely neglected; the treatment was, for the most part, purely mechanical, and partly thence, partly from the inadequacy of the mechanical apparatus, was imperfect, and in most cases, even hurtful. Only in modern times has this treatment become the object of careful inquiry, and employed on right principles, according to the difference of the causes of curvature. A survey of the various machines and contrivances which have been proposed for the treatment of the spinal curvature, give proof of this.

1355. The apparatus which have been proposed for cure of spinal curvature, act either by *pressure* or *extension*, or both together.

1356. To the apparatus, acting by pressure, belong

First. Heister's *iron cross* (*b*), which consists of two flat iron rods connected together in form of a T. On the transverse piece are two rings, by which the shoulders can be drawn back; at the extremity of the vertical piece descending along the back is a strap, by which it is attached to the body. B. Bell (*c*) has added to this machine a padded neck-band,

---

(*a*) Delpech, above cited.

(*b*) Institutiones Chirurgicæ, pl. viii. f. 13.

(*c*) Lehrbegriff, vol. v. pl. iv. f. 5, 6, 7.

connected to the cross by an iron rod, which may be fixed higher or lower, in order to keep the head more or less up.

Second. Van Gesscher's *apparatus* consists of a stirrup bound around the *pelvis*, on which two rods are attached with screws running upon the sides of the spinous processes, and rivetted above to a shoulder-piece, on the two ends of which are straps to draw the shoulders back.

1357. To the apparatus operating by extension, belong, first of all, the *extending beds* and *stretching apparatus* of Venel and Schreger (*a*), Lafond (*b*), Shaw (*c*), Maisonabe (*d*), Blömer (*e*), Langenbeck (*f*), Delpech (*g*), Heine, and others, in which the patient is fastened, by means of padded straps applied on the feet and head, above and below to a bed or chair, and the extension of the whole body is kept up by sufficiently strong springs. In some of these machines it is attempted simultaneously to employ pressure, by means of solid pillows thrust beneath the back, or as in the stretching apparatus of Delpech and Langenbeck, by elastic traces carried around the body from one to the other side of the bed. The same object is effected only momentarily, by the so-called *neck-swing* (*escarpolette*) of Clisson, in which a broad cloth is applied around the patient's neck, and to its two sides is attached, behind the ears, a bandage which is carried through a pulley attached to the cieling, wherewith the patient draws himself up as long as he can bear it.

Here also belongs Le Vacher's machine which consists of stays, laced in front, and having a plate attached to its hind part. An iron rod passes into a groove upon this plate, which ascends straight up the middle of the neck and thence curves over the head to the forehead. In the notch at the upper end of this rod is hung an apparatus which is fastened around the head and beneath the chin of the patient. Pelug (*h*) has improved this machine by attaching, instead of the head-apparatus, at the end of the iron rod which reaches only to the upper part of the neck, a neck-band, by which the chin and *occiput* can be held up. Sheldrake altered Le Vacher's machine; he took away the stays and fastened the iron rod on a plate which descended from the middle of the back and fitted closely to the rump-bone. Delacroix also altered this machine, making its point of support on the *pelvis* (*i*). Guerin (*k*) has proposed an apparatus for the simultaneous extension (*extension sigmoide*) of the vertebral column in contrary directions of the curvature.

Hereto also must be referred Darwin's (*l*) advice, to keep the patient, at the onset of the curvature, for a long time in the horizontal posture, and if this be insufficient, to let him sit on a particular kind of seat, in which, by a special contrivance, the shoulders can be raised and the head supported. Blœmer and Lafond's stretching-chair (*m*).

1358. The apparatus acting by extension and pressure, are—

First. Schmidt's *apparatus* (*n*), consisting of two semicircles connected together, which lie upon the hip-bones and from whence rise up two sheaths

or the reception of two rods, which at their upper part have a semicircular sweep outwards for supporting the shoulders, and are movable higher or lower. At the upper part of each sheath is a semicircle, to which two rods are attached, their upper ends thrown round the half circles, like hooks, their lower ends curved round the half circles, encompassing the *pelvis* and ascending within it. These processes, covered with leather, form long pads, which are brought close to, or separated from, the rods, by screws. Well-fitting stays surround the front of the chest. The apparatus of Langenbeck (*a*) and von Graefe (*b*) are constructed on the same principles.

Second. Jörg's *apparatus* (*c*) consists of a firm and an elastic part; the former is made of linden wood, covered with soft leather; the latter consists of several springs laid close together and covered, connected at the one end with the firm part and at the other end fastened with a buckle. In *scoliosis* the firm part is applied to the concave side of the trunk, below it rests upon the hip, and above, juts against the shoulder. The elastic half is carried round the other side (for the first degree of *scoliosis*, Jörg employs an elastic brace, which is attached to the breeches usually worn, before and behind, in the middle by a button, and passes over the shoulder of the projecting side, where a pad is placed beneath it.) In *cyphosis* this apparatus is applied with the alteration, that the firm part is always applied where the trunk is concave, and the elastic half on the seat of the projection.

A. Portal had already proposed to a certain extent a similar apparatus, consisting of a double fork, which is fastened on the sides to a pair of stays, so that the arm above and the hip below serve for its application (*d*).

The Graefean apparatus is composed—1. Of a *loin-girdle*, which by means of a pair of semilunar plates rests upon the crests of the hip-bones. The hinder ends of this girdle may be introduced into each other, and fastened with a screw. The front ends are connected with a buckle. Upon the semilunar plates are studs on both sides, on which is fastened a strap, destined to support the belly. All this part of the machine is stuffed with hair and covered with leather. 2. Of a *breast-girdle*, which like the lower one consists of two semicircles, connected behind in the same way as is the lower one; and in front, in males, fastened together by a strap and buckle; but in females, segments are applied around the breasts. 3. On the loin- and chest-girdle there are, on both sides, two rods firmly connected with the former, and with the second by a steel plate. These rods form beneath quadrangular sheaths, which terminate in quadrangular capsules, on the outside of each of which is a quadrangular prominence. In the interior of these sheaths is an endless screw, which can be raised up or depressed by means of a roller fixed on the quadrangular projection. The rest of the sheath above the quadrangular process is formed into a cylinder, in which is a spiral spring. Into the upper opening of this cylindrical part of the sheath is the rod received, having upon it the support for the shoulder, which is properly padded, and so attached to the rod that it can be differently placed, according to the different form of the shoulder. For the purpose of connecting pressure on the spine with this extending apparatus, cushions are applied, by means of screws on the breast or loin-girdle, according to the difference of place to which pressure is to be applied.

I have made the following alterations in this apparatus to render it more simple and less costly. A case of iron plate, properly padded, and enclosing the *pelvis* up to the upper spine of the hip-bone, is fastened in front with a broad strap and buckle. On both sides of this *pelvis* case are two buckles, in which two rods connected with each other are inserted. At the upper end, these rods are connected with an iron plate, through the middle of which a screw passes, quadrangular at its lower end, and at the upper, the properly padded supports are attached, which may be placed higher or lower, by means

(*d*) Précis de Chirurg. prat., vol. i. Paris, 1761.

of a key fitting the quadrangular end of the screw; thus the apparatus acts like Graefe's. For the purpose of making graduated pressure I do not employ cushions, but elastic bands, (after Joërge's plan,) which in *cyphosis* lie upon the back, and are attached to brass studs on both rods; but in *scoliosis*, to the studs on one rod over the projecting side of the trunk, between it and the ascending rod, for the purpose of surrounding the whole body, and again is attached to the stud of the first rod. In inclination in two opposite directions, this yoke may be applied, also in contrary directions. If the shoulder-blade particularly project, I carry an elastic band over the more elevated shoulder, and fastened behind and before to that going around the body. I allow this apparatus to be worn day and night over a close shirt. From its careful employment I have derived the happiest results (*a*).

1359. It were superfluous to enter on a special criticism of the several apparatus. Those contrivances only which at once effect extension and pressure can act efficiently. Of the portable apparatus of this kind, those only answer the object which have their point of support on the *pelvis*, and are so constructed that they cause no painful pressure, nor too great compression of the chest, and so on. With proper consideration of the points still to be mentioned in reference to special treatment, the cure may indeed be effected with these apparatus in incipient and slight degrees of curvature, and specially in lateral curvature produced by unequal muscular activity, as I have so frequently had opportunity to observe in the use of my above-described apparatus, which is distinguished from that in which pressure is made by the cushions, by the lateral elastic bands. Such favourable result is, however, only possible with close and careful attention, and when, especially, all the circumstances of the patient are properly regulated. When this is not the case, the disease becomes really worse, or at least all the time is lost which could have been best employed for the cure of the deformity. For all great degrees of curvature, such treatment is insufficient; a continued employment of the extending apparatus is necessary, the operation of which is not equally certain as that of the portable apparatus, and among which that is best, in which, at the same time, bands are attached, to operate on the opposite sides of the trunk, as, for instance, in the extending apparatus of Delpech, Langenbeck, and others.

1360. Such treatment can only in reality be carried on with suitable care in special institutions for the purpose; and this is the reason why of late these (orthopedic) institutions have become so very numerous. There is, however, a well grounded complaint, that in many of them the entire treatment is conducted in a too mechanical manner; and that by too long continued use of the extending apparatus, with constant rest, the greatest injury is caused to the whole constitution of the patient; so that, as I unfortunately have seen in several cases, with slight or merely transitory improvement of the curvature, disorder of the health difficult to be got rid of, and even incurable, has been thereby produced.

Those cases are not to be now considered where the disease of the spine is of a completely different kind, and not to be thus treated.

1361. Delpech has the great merit, by combining a regular course of gymnastics with the use of the extending apparatus, of getting rid of those disadvantages which have been properly objected to on account of the above-mentioned causes, by the usual employment of the latter, and especially by the proper estimation of the operation of such gymnastics, of having opened a new and very successful path in the treatment of this deformity.

(*a*) Gruber, S. P. G., Dissert. de novâ machinâ Cheliusianâ ad sanandam gibbositatem, cui accedit hujus morbi descriptio. 1825. 4to.; with copper-plates.

1362. These gymnastics have the especial object of relieving the *vertebræ* from each other's weight for several hours daily; of supporting the weight of the body, without condemning it immediately to rest and its ill consequences; of exciting the activity of the muscles to sufficient continuance and power, so that it may be advantageous to the nourishment of these organs, and to the improvement of the whole constitution; to employ all the muscles, without exception, in increased exertion, and by means of motion, extension, and pressure, employed in all directions, to reach the affected parts of the spine. These exercises are to be used daily for two or three hours, and then, according to the state of the deformity, the necessary extension in the stretching-bed, or some special apparatus is to be employed. DELPECH considers swimming as very proper, but otherwise he does not use bathing, if no special reason call for its use; neither does he employ friction and the like, because by the exercises the muscles are acted on far more properly and more powerfully than by those means.

These exercises, which are undertaken gradually, and extended to all the muscles, are, movements upon the swing, exercises and games on the spiral ladder, exercises on the knotted rope, games on the loose rope and climbing pole, games on the obliquely-stretched rope, on the straight and obliquely-stretched ladder, games on the tight rope and flying bridge, the use of a windlas, games with the horizontal pole, and so on. The atlas accompanying DELPECH's work gives a sufficient representation of these different exercises.

Where no special institution is at hand, apparatus for these exercises must be introduced into every room, yard, .or garden. I have for several years (in my private practice) employed such appropriate gymnastic exercises, in connexion with other remedies in the treatment of curvatures, with the desired results.

1363. If the cause of the curvature be in an unequal contraction of the muscles, in which ordinarily the left side sinks down, the right shoulder-blade projects, and the right shoulder is raised, it must be treated according to the general rules laid down. It is usually attempted by rubbing in suppling ointments, or oily remedies to relax the contracted muscles of the sunken side, and by rubbing opodeldoc, *spiritus serpylli c. liq. ammon. caust.*, *tinct. canthar.*, with some volatile additions, to excite the muscles of the protruding side to action. For these cases the employment of electricity, repeated blisters and the *douche* upon the side of the extended muscles, have been also recommended. In the rubbings, which are to be performed night and morning, the patient should be stretched on his belly, and they should be continued from half to a whole hour, and attempts are, in the mean time, to be made to press the spine into its natural direction. These rubbings operate certainly less through the substances rubbed in, than from the pressure, kneading, and stretching of the contracted muscles. If the nervous activity be in these cases diminished, the rubbing should be more active; spirituous remedies, and even the application of stronger irritating remedies are indicated. In incipient *scoliosis*, if care be taken that the patient carry himself properly, that the two halves of the body be equally exerted, that all faulty posture in writing and the like be diminished, that he often hang by his hands, and keep the horizontal posture in bed, upon a hard mattrass, a perfect cure may be effected. Here also well-fitting stays, with whalebone or elastic springs, will be of much use, as they properly support the body (1). In more considerable curvature, regulated gymnastic exercises, the use of a properly constructed portable apparatus, or better, the employment of a stretching apparatus, is most suitable. In these cases, the *scoliosis* does not usually affect the general state of health, and we see that the mechanical means are best endured. If the constitution be at the same time affected, corresponding remedies and suitable dietetic care must be employed.

(1) The prejudices which have been very properly made to the stays (*a*), has no reference to this determination of their employment.

1364. For the quicker cure of curvatures of the spine, depending on muscular contraction, Guérin (*b*) has proposed the division of the contracted and shortened muscles, and practised it in several cases. The muscles which he cut through were *m. cucullaris*, *rhomboideus*, *levator anguli scapulæ*, *sacro-lumbalis*, *longissimus dorsi*, and *semi spinales*. He has performed the division in persons of both sexes, and of different ages: the youngest was thirteen, and the oldest twenty-two years of age. All the curvatures were in the second and third degrees, with distortion of the spine and corresponding humps. In some a single division of the shortened muscle was sufficient; in others a second and third was undertaken. In all he obtained, immediately after the operation, a very striking degree of straightening of the spinal column; and in a man of twenty-one years of age, whose curvature had been subjected to a ten months' mechanical treatment, he effected an immediate straightening by cutting through the *m. longissimus dorsi*, and the corresponding *m. semi-spinales*, In other subjects he carried on the treatment by mechanical means with decidedly good effect. Although the subcutaneous division of the muscles of the back has been undertaken by other persons, I cannot, from the practice in question, give so decided judgment of its fitness, as the numerous and careful observations upon tenotomy in other curvatures have allowed.

[In regard to the division of the muscles for the cure of curvature of the spine Robert Hunter of Glasgow (*c*) says:—"In no instance has the operation of itself produced a cure; but in all the cases on which I have operated, with one exception, it manifestly placed the patient in a more favourable state for the performance of a cure. The operation itself appears to me to effect no more than to take off, either in part or whole, the power of muscles that are interested in maintaining the curvature, and thus placing the spine in a condition to be more easily influenced by mechanical and physiological causes. The cases which have been treated by me have all been of long standing, none less than seven years, and some ten, sixteen, and twenty years, and all with considerable torsion and gibbosity, as well as lateral curvature. * * * In some instances the section of the muscles was instantaneously followed by an obvious improvement in the state and appearance of the back; in other instances I could discover no change whatever.

"I perform," says R. Hunter, "the subcutaneous section of the dorsal muscles at four different places of the back. 1st. I weaken the tension of the deepest-seated layer of muscles—that formed by the *multifidus spinæ*, by dividing the thickest part of that muscle, as it lies comparatively superficially upon the *dorsum* of the *sacrum*, opposite the posterior superior spinous process of the *ilium*; 2nd and 3rd, I remove the tension of the middle layer of spinal muscles, that formed by the *longissimus dorsi* and *sacro-lumbalis*, by cutting these muscles across, sometimes in the lumbar region, and sometimes in the costal region, according to the circumstances of the case; but more frequently in the lumbar region, near the origin of these muscles; 4th, to destroy the tension of the flat and more superficial muscles, I divide these muscles by a longitudinal incision, close to the spinous processes of the *vertebræ*, at the place where the tension of the muscles appears to be the greatest. In one instance I cut through, with considerable affect, the *latissimus dorsi* at the side of the chest, and consequently at some distance from the spine. The muscle crossed the contracted and concave side of the trunk, and appeared to be accessory in huddling in the ribs of that side. When the patient

---

(*a*) Soemmering, S. T., Ueber die Schadlichkert der Schnurbruste. Berlin, 1793.

(*b*) Gazette Médicale de Paris. 1840. No. 14, 15.

(*c*) On the Section of the Muscles in Spinal Curvature; in London Medical Gazette, vol. xxxii. 1842.

attempted to elongate that side, a cord, as thick as the little finger, was seen stretching from the crest of the *ilium* to the *scapula*; as soon as this rigid cord of muscle was cut through, the ribs became less huddled together, and that side could be elongated to a much greater degree, and the spine materially affected. The cutting of the dorsal muscle is only the first, though an important step in the treatment of spinal deformities. The means that are afterwards employed in conducting such cases to a successful issue, are both mechanical and physiological. The first consists in the application of pressure, made in various ways, and by various means, to assist in the gradual return of the parts to their natural places; and the second, without which the first would be useless and unavailing, consists in infusing power into the muscles which have become weak or dormant from disease, by simply calling these muscles frequently, and in various combinations, into action." (p. .)

In reference to the division of "certain muscles of the back, on the contracted state of which it was alleged the distortion depended," SYME observes, "nothing could be more erroneous than this view of the case, since the muscles throughout its production and existence are entirely passive. They, from the first, do not draw the spine away, but allow it to bend, their fault being weakness, and not undue contraction, so that those requiring to be connected are seated on the convexity of the curve, instead of its concavity, and it is needless to add, could not be strengthened by division of their substance." (p. 271.)

I have not had any experience upon the subject, but am rather disposed to agree in opinion with SYME.—J. F. S.]

1365. In curvatures dependent on great muscular weakness, internal tonic remedies must be employed, as bark, acorn coffee, and the like; a strengthening succulent diet, the use of generous wines, chalybeate mineral waters, rubbing in volatile, aromatic, and spirituous remedies, steel, salt, or aromatic bathing, river bathing, and so on. In these cases the gymnastic exercises are especially effective, and, by their proper arrangement, the injuries are more certainly prevented, which otherwise are necessarily produced by rest and inactivity of the muscles, accompanied with the use of the stretching apparatus. In children who begin to walk, it is usually sufficient to rub the back and lower limbs with spirituous remedies, to prevent sitting, and to let them sleep upon a hard mattrass.

In the high shoulder attempts must be made to relax and continually depress the too violently acting muscles, by proper rubbing, proper carriage and exercise, for which purpose the one-sided breeches brace, recommended by JÖRG, is most suitable. In high back, if there be at the same time a bowing forwards of the head, the machine recommended by SHAW (*a*), is best, by which the muscles of the nape are put in greater activity, and drawing back the head is effected.

1366. If the curvature of the spine depend on softening and thickening of the fibrous inter-cartilage, the readiness with which, by extension, the direction of the spine can be changed, renders it in the highest degree proper. If, by pressure, movement between the several *vertebræ* can be brought about, there is no need of making any attempt at extension, nor of employing any other means which act forcibly on the *vertebræ*. The altered joints must first acquire more firmness. If, at the same time, there be pain, which, although not symptomatic of inflammation, leads to the belief of a passive gorging of the blood-vessels, a condition which by neglect passes on to inflammation and suppuration, leeches and cupping are to be first employed, though not to excess; afterwards rubbing in volatile camphor liniment, blisters, issues, cold *douche* bath, warm *douche* bath of salt water, of water containing sulphuretted hydrogen, even *moxas*, especially on the principal seat of the deformity. The patient should observe a quiet posture on the back, and afterwards cautiously use the easiest gymnastic exercises; for instance, the motions

---

(*a*) Engravings, pl. vii. f. i., and described in his Essay on Distortions, already quoted.

with the barrow and rope. The patient's powers must be supported by a nutritious diet and proper medicines.

If the nature of this ailment be ascertained only by the horizontal posture, or by careful attempts at extension, if no other pain exist than that caused by careful extension, if it be not increased by pressure on the painful spot, and if it decrease by resting quietly on the back, the gymnastic exercises may be at once begun, with caution; then followed by the employment of extension; and lastly, the lateral bandages (*a*) may be also employed.

1367. In curvature of the spine depending on rickets, the treatment must be especially directed towards the improvement of digestion and chylification, by tonic remedies and strengthening diet; aromatic and spirituous rubbings, strengthening baths, lying in the open air upon a sand-bank, warmed by the sun, are to be employed; horizontal posture upon a hard mattrass, and subsequently, gymnastic exercises and the extending apparatus are to be carefully made use of. The treatment is similar in *osteomalacy;* bark with phosphoric acid is here especially efficient, as I have repeatedly observed. The very severe pain often occurring in these cases, must not lead to the application of leeches, and so on. Besides proper position, and support of the body in general, nothing further can be done in these cases against the curvature.

1368. If the curvature be connected with rheumatism, a correspondent treatment must be employed; and the complication having been got rid of, the treatment of the curvature must be thought about. Palsy of one or several muscles often occurs from rheumatism; in such cases, moxas, *douche* baths, purgatives long continued, and the like, are very efficient.

Curvatures of the spine, from contraction of one side of the chest, after the cure of an *empyema*, or abscess in the lungs, are incurable, and every attempt at their treatment inadmissible and dangerous. Curvatures from shortening of one of the lower limbs, may, in many instances, be prevented by a peculiar shoe and the like, by which the proper length of the limb is attained.

III.—Of Curvatures of the Limbs.

[The several portions of the lower limbs are occasionally and variously curved and contracted upon each other, either as original imperfect developments, or resulting at any period of life from different causes, which may be either inflammatory, or from paralytic affection of one set of muscles, whilst their antagonists still possess their contractile power, and, being unopposed, draw together more or less completely those portions of the limb to which they are attached. The fixedness of the limbs from either of these causes must not be confused with that depending on *anchylosis*, already considered (*par.* 224*) (*b*) in which, after more or less complete destruction of their cartilages, the joint-ends of the bones are fixed in any position they may have acquired, during the progress of the disease, by a fibrous or bony union. The cases now to be considered depend entirely upon the condition of the muscles, their tendons, and tendinous sheaths, whilst the joints themselves have their structure entirely changed, or but very little altered; and in such only can surgical treatment be of any avail.

(*a*) Delpech, Orthomorphie, vol. ii. p. 238.

(*b*) Vol. i. p. 241.

1.—OF CURVATURES OF THE LOWER LIMBS.

Curvatures of the lower, are more frequent than those of the upper limbs, although the bony and muscular fabric of the former are much more strong and powerful, partly because the weight of the body resting upon them more readily produces curvature, under the existence of favouring circumstances; and partly because in most cases, in incipient and even in advanced curvature, walking produces an injurious effect upon the lower limbs. Of the several joints of the lower extremity, curvature is least frequent at the hip, and most common, and indeed not infrequent, at the ankle, at which also it is most generally an original malformation.

A.—OF CURVATURES OF THE HIP.

Curvature or contraction of the thigh upon the belly (*Scelocampsis*, Lat.; *Angezogensein des Oberschenkels an den Unterleib*) may originate in the continued action of the flexing muscles of the thigh, whilst their antagonists are palsied from any cause, or from sympathetic affection of the former muscles, with disease of the *vertebræ*, which is sometimes consequent on *metastasis*, or from inflammation in the *m. psoas*.

The *treatment* of these cases consists in relaxing the contracted muscles by suppling applications, and in exciting the inactive or palsied muscles to action by the use of irritating remedies; and if these fail, the division of the flexing muscles, to wit, the *m. pectineus* and *sartorius* has been proposed and performed by Stromeyer (*a*), but which, as far as I am aware, although successful, has not been repeated by any one else.

In a case of metastatic inflammation of the spine following measles, in a child of ten years, in which the thigh, at first drawn close up to the belly, by yielding of the lumbar muscles after the use of tartarized antimonial ointment, blisters, and rubbing in mercurial ointment, could be drawn down to a right angle, Stromeyer divided the *m. pectineus* and *sartorius* with success. The division was made in the following manner:—One assistant fixed the *pelvis*, whilst another stretched the contracted thigh, which raised the *m. pectineus* so that the finger could be passed behind it from its outer side, an inch and a half below its origin. A strong *phimosis*-knife was then introduced upon the finger through the upper half of the muscle, dividing it, and penetrating the skin. He then cut through one half of its breadth beneath the skin, and afterwards divided the second inner and under half; and only a few drops of blood followed the four little punctures made in the operation. The *m. sartorius* was divided, by adducting the knee so as to make the muscle prominent; and having raised it with the thumb and finger of the left hand, he thrust a *phimosis*-knife through, about two and a half inches below its origin, and divided the muscle beneath the skin, the ends of which separated rather more than half an inch. The leg immediately straightened without the least difficulty, and having been kept on an extending apparatus for a fortnight, was allowed to get up, and in the course of three months walked about well. (pp. 119, 20.)

B.—OF CURVATURES OF THE KNEE.

Curvature of the knee may be either congenital or acquired, and depending on imperfect development of the muscles, tendons, and *fasciæ*, or on their shortening consequent on inflammation, either of the structures themselves or of the cellular tissue around or in the neighbourhood of the joint, or simply from inaction. This condition is to be distinguished from the curvature which almost invariably accompanies *anchylosis* following ulceration of the joint-cartilages, and which has been already considered.

(*a*) Above cited.

One knee may curve or bend inwards, producing the deformity called *In-knee* (*Genu valgum*, Lat.; *Ziegenbein*, *Schemmelbein*, Germ.; *Genou en dedans*, Fr.) or *Knock-knees*, when both knees are in like manner affected. It is characterized by a projection inwards of the inner condyle of the thigh-bone, with a less or great divergence of the leg and foot outwards, so that in standing the feet are far apart from each other, and the thigh-bones, overhanging the inside of the heads of the shin-bones, are, together with the weight of the body, supported mainly by the internal lateral ligaments of the knee-joints. The knees also, instead of being against the same imaginary plane, are placed one behind the other. When this deformity is great, walking is very awkwardly performed, as it is necessary, in bringing the leg forwards, to abduct it considerably, to avoid striking the knees together; and in consequence of the oblique direction of the leg, the inner ankle also bends inwards and the person treads upon the inside of the foot.

This is a very common ailment in labouring persons who carry very heavy weights, but is generally worst in those accustomed to wheel heavy barrows. It, however, is by no means unfrequent in young people who grow quickly, but is often recovered from, as their bodily strength improves, unless occupied with hard labour.

Little can be done for this distortion, which I have in one or two persons known to incapacitate from following any laborious employment, besides supporting bandages and cold *douche* baths. Although irons are recommended, I have not seen much benefit from them.

The knee may also be curved outwards (*Genu varum*, Lat.; *Säbelbein*, Germ;) this is, however, rare, and must not be confused with the so-called *bow leg*, which depends principally on outward curving of the shin-bone, and to which the slight outward bend of the knee is only consequent.

The knee is, however, most commonly bent forwards, (*Contractura Genu*, Lat.; *Vorwärtsbeugung des Kniees*, Germ.,) and this may occur from original shortening of the bending muscles of the leg, or of the *fascia* covering the thigh, an account of which last was first published by FRORIEP (*a*), who found, in a corpse, that although the flexing muscles were cut through yet the knee could not be straightened. Very frequently the knee is bent at a later period of life, and the most common causes are rheumatic inflammation of the tendinous structures about the joint independent of disease of its interior, or scrofulous inflammation running on to suppuration, around or even in the joint itself. Palsy of the extending muscles may also give rise to this kind of bending of the knee.

The *treatment* of these cases consists in rubbing and in the application of extending apparatus and the use of passive motion, from patiently persisting with which for a long period, considerable benefit and occasional cure results; but in those cases which cannot be managed, it has been recommended to divide the hamstrings, an operation, I believe, first practised by MICHAELIS (*b*), who had performed it three times previous to October, 1810, and it has since been occasionally performed with varied success. The operation is performed, either by division of the hamstring tendons at once, or by partial and repeated cuts till they are completely divided, using at the same time an extending apparatus as the patient

---

(*a*) Chirurg. Kupfert, No. 346.

(*b*) Ueber die Schwächung der Lehnen durch Einschneidung; in HUFELAND and HUMBY'S Journ. der prak. Heilk., vol. vi. p. 1.

can bear it. Objections, however, have been made to the operation, that in consequence of the often long-continued bent position of the leg, the joint surfaces in the knee are so much altered in form that they cannot retain their reacquired natural position, and consequently dislocation of the shin-bone backwards occurs (1). The operation is performed by passing a *phimosis*-knife between the hamstring and the bone, or between it and the skin, taking care to avoid the *peroneal* artery and posterior *tibial* nerve (2).

(1) FERGUSSON, of King's College, informs me, that in two or three instances he has seen dislocation at the knee occur after division of the hamstrings for contracted knee, and has been obliged to amputate the limb.

(2) STANLEY (*a*) operated on a case of contracted knees two years after *paraplegia* consequent on sleeping in a damp bed. "Each knee-joint was immovably fixed in the state of extreme flexion; the ham-strings were contracted and rigid; and the cellular tissue around them had become indurated, and firmly agglutinated to the tendons, whereby their outline could not be distinctly traced. * * * To avoid all risk of injuring the popliteal or peroneal nerve, he deemed it prudent to divide the rigid hamstrings, and the surrounding indurated cellular tissue, by small subcutaneous incisions many times repeated in both limbs, applying after each operation the apparatus for extending the knee-joint." By this proceeding, after many months, the joints slowly straightened, and became movable; but, the action of the ankle-joints being impeded by the rigidity of the ACHILLES' tendons, STANLEY divided these, and afterwards the extensor tendon of each great toe, as it was rigid, and kept the toes constantly raised. Warm baths and friction were employed for suppling the limbs, and, at the end of eighteen months, the case was perfectly cured.—J. F. S.]

C.—OF CURVATURES OF THE FEET.

1369. The feet may be curved in various ways; thus, they may be turned inwards *(Vari)* or outwards, *(Valgi,)* or the sole of the foot and the heel may be inclined so backwards and upwards, that the entire sole shall have the same direction as the leg, or the foot may be so drawn forwards and upwards towards the shin-bone, that the point of the heel alone touches the ground. The first kind of curvature is called *Club-foot;* the second, *Splay-foot;* the third, *Horse-foot;* and the fourth, *Heel* or *Hook-foot (Pied-bot calcairen* of SCOUTETTEN.)

DUVAL (*b*) includes the various curvatures of the foot under the general name *strephopodie,* and distinguishes varus as *strephendopodie,* valgus as *strephexopodie,* horse-foot as *strephocatopodie,* its highest degree as *strephypopodie,* and heel-foot as *strephanopodie.*

1370. *Club-foot* is that deformity in which the foot is so twisted on its long axis, that its inner edge is raised, the outer turned downwards, and the sole of the foot with its back brought more or less vertical. The toes are strongly bent, the back of the foot more convex, the sole more concave, and the heel raised, and inclined inwards, so that it does not touch the ground. The whole foot is unnaturally turned inwards. Upon the back (instep) of the foot, a considerable prominence is formed by the head of the *astragalus;* the Achilles' tendon is much stretched. Walking is more or less interfered with; the patient cannot tread upon the sole of his foot, but only on the middle of its outer edge, and, often only on the outer part of the back of the foot, where commonly a large callosity or mucous bag is enlarged or newly formed. The patient is never able to bend his foot by muscular power; but, in making the attempt, he rather adducts the foot already inclined inwards.

1371. Club-foot has various degrees. When slight, the curved foot may be brought back to its natural position, and the prominence on its back then disappears; but the foot again treads in its unnatural posture when walking is attempted. In the higher degrees, the foot can never be at once brought to its natural position, and often can scarcely be moved in that direction. In these motions of the foot, the fibres of the *m. gastrocnemii* and *tibialis anticus*, and the plantar *aponeurosis*, which are always more or less stretched, oppose the straightening of the foot.

1372. This malformation, which has been noticed as hereditary, is either congenital, or occurs subsequently. In the former case, which is the most common, the club-foot arises as consequence of arrested development; of a continuing, excessive activity of the bending muscles of the foot, as has been often observed in a three months' *fœtus;* or as consequence of peculiar position of the foot during pregnancy, and therewith also deficient innervation depending on diseased activity of the brain, and nervous system. After birth club-foot may be developed by wounds, by palsy of muscles, by spasm or *neuralgia*, and if the foot have been kept a long while in a particular posture by an ulcer, or any other painful circumstance, by which shortening of certain muscles is produced. The disturbed antagonism of muscles (contraction of those attached to the sole, and to the inner edge, extension of those to the outer edge, and back of the foot) is the special cause of this malformation; all the changes which therewith occur in the ligaments and bones are merely secondary symptoms.

The shortened muscles are *m. tibialis anticus*, and *posticus*, *gastrocnemii*, *soleus*, and *plantaris*, the plantar *fascia*, *m. flexor longus digitorum pedis*, *abductor pollicis*, *transversalis pedis*, *flexor brevis minimi digiti*, *flexor longus*, and *brevis pollicis*. The lengthened muscles are *m. peroneus longus*, *tertius*, *brevis*, *extensor longus* and *brevis digitorum pedis*, *abductor minimi digiti*. All the ligaments on the plantar surface, and on the inside of the foot, are shortened, as, on the contrary, those on its back and outer edge are lengthened. The tarsal bones are herewith, according to the degree of curving, more or less removed from their mutual contact, without entirely leaving the sockets or hollows, in which they had been received. The navicular, the cuboid, the heel-bone, and *astragalus*, especially change their position, and are twisted on their small axis. If club-foot exist long, the bones are fixed in their unnatural position, and more or less changed in their form.

Opinions as to the cause of club-foot are very various. The notions of **Paré** and others, who held it to be the consequence of long sitting during pregnancy, with the legs twisted over each other, or from pressure of the feet in washing and carrying children, are merely to be mentioned. **Duverney** (*a*) fixed the cause of these curvatures in the muscles, and derived it from the unequal stretching of them and of the ligaments. **Scarpa**, as well as **Brüchner** and **Naumberg**, believed that vicious twisting of the foot first exists, and thereby is caused an approximation of the points of insertion of some muscles, and the distancing of others from their fixed points; consequently, a shortening of the former, and an elongation of the latter. **Wantzel** considers club-foot as great adduction, accompanied with violent extension, whence necessarily are the corresponding consequences; and **Jörg** holds it as a continued adduction, become habitual to the foot. **Delpech** (*b*) has of late withdrawn his previous opinion that the cause of club-foot is in the form of the bones, because the muscles do not oppose a contrary direction of the foot, which is especially distinct in those cases where the shortening is accompanied with atrophy, and with a sort of palsy. He considers the congenital, or accidental shortening of the muscles, as the peculiar cause of club-foot and, at the same time, has pointed out the retraction of the plantar *fascia*. **Rudolphi**, who has several times seen this deformity in the *fœtus* of from three to four months, derives it from arrest of the nervous influence, contrary to the opinion put forth by **Camper** and **Glisson**, that the club-foot arose from vicious position of the child in the womb, by which the foot was pressed on, and its development prevented; an opinion in which **Cruveilhier** (*c*) has participated, and **Martin** (*d*) has sought to ground in pressure of the womb from deficiency of the waters. **Scoutetten** holds the following as the causes of congenital and postgenital club-foot. 1. Unequal division of power between the extending and flexing muscles; 2. Vicious condition of the joint surfaces of the tarsal bones; 3. Vicious position of the *fœtus* in the womb; 4. Compression of the flexible joints by contraction of the womb; 5. Convulsions of the child in the womb; 6. Convulsions in early childhood; 7. Chronic inflammation of the muscles of the leg; 8. Vicious innervation, dependent on disease of the brain, or spinal marrow, without previous convulsions; 9. Contraction of the plantar *fascia*; 10. Contraction of the muscles, without discernible cause. **Duval** (*e*) assumes as causes of congenital club-foot, (as well as of the other curvatures,) vicious position of the foot in the womb, and disturbance of the functions of the brain and spinal marrow. Consecutive or accidental curvatures he derives from wounds, fractures, dislocations, bad holding of the foot, from inflammation, abscess, and so on. With all these causes, unequal activity of the muscles exists. **Blasius** (*f*) puts forth the congenital club-foot alone as the *true* one; in it the above-described symptoms are found. That occurring after birth, which usually is not so great, and is produced by wounds, ulceration, palsy of the muscles, dyscrasy, and neuralgy, is a natural extension of the foot, caused by too violent contraction of the muscles of the calf, in which the turning around the long axis of the limb follows only secondarily from walking. This he calls the *seeming* club-foot.

Club-foot is, according to **Little**, easily distinguishable from that deformity of the

(*f*) Klinische Zeitschrift für Chirurgie und Augenheilkunde. pt. i. p. 60.

tarsus which is caused by rickets. The participation of the parents in the disease, the usual complication which accompanies rickets; above all, the curvature of the bones of the limbs, serve as sufficient diagnostic marks. The *pathognomonic* signs, retraction of the heel, stretching of the tendons of the muscles of the calf and the adductors, concavity of the sole of the foot, and the curvature of the inner edge of the foot are wanting.

On anatomical examination the bones appear in *varus* to be brought out of their position, without prejudice to their natural firmness, from muscular activity, and the weight of the body; in *false varus*, which arises from rickets, the bones are not only brought out of position by the weight of the body, but also compressed and misformed, in consequence of their softening.

[The following interesting case of club-foot was under my care some years ago, in which the cause was at first very doubtful, and led to several operations; but subsequently I think there could be little doubt that it was hysterical.

Case.—S. P., aged seventeen years, a stout, healthy girl, was admitted

April 9, 1837. She has been irregular for several months, and has had three fits, but of what kind cannot be ascertained. About a month ago she went to bed seemingly quite well, and with perfect use of her limbs; but, when she awoke in the morning, her right foot was immovably fixed, with the sole turned upwards and inwards, so that when put to the ground, the limb rested on the whole length of the outer margin of the foot. This was accompanied with great pain along the course of the *m. peronei*.

At the present time the foot is firmly fixed at right angle with the leg, and the sole faces directly inwards, the *m. tibialis anticus* is in strong action, and its tendon raising the skin in front of the ankle-joint. No other tendon or muscle is unnatural. Any attempt to restore the proper position of the foot causes great pain in the course of the contracted muscle.

In the course of the two following months, a moxa was thrice applied on the calf of the leg, with the hope of stimulating the antagonist muscles to action, but without benefit.

May 18. She was attacked with pain on the inner edge of the calf of the leg, followed by a little swelling, as if the *m. gastrocnemii* were in action at that point, and accompanied with slight tenderness. These subsided in the course of a few days, and her condition otherwise remained unchanged.

June 15. A stream of cold water was ordered to be poured on her leg, from a height of five or six feet, for a quarter of an hour every morning. This was persisted in for three weeks, occasionally followed by pain; but then given up, as there was an erysipelatous blush about the ankle, which, however, soon subsided.

July 10. A moxa was put in opposite the origin of the sciatic nerve.

July 14. Complains of pain on the outer side of the calf, but more severe than before and accompanied with swelling of the muscle; these have been coming on for the last three days, and the swelling is about the size of half a walnut, tender, but not firm though very distinct.

On the following day she was electrified in the whole length of the *m. peronei*, and from them across to the *m. tibialis anticus*. This was continued daily for a short time and she fancied she could move her great toe a little.

July 21. One or two electric shocks were also passed through the region of the womb, in hope to excite it to action; but, after repetition for two or three days, was given up as it produced great pain in the *pelvis*, without other effect.

Aug. 9. The electric shocks having blistered the front of her leg, sparks were ordered to be taken daily instead. About a fortnight or three weeks after, the anterior tibial muscle certainly had yielded, and she was able to get the sole of the foot flatter upon the ground, and walk a little better. This, however, lasted only a fortnight, and the foot then gradually reverted to its old position, if not worse. The electricity was therefore given up, and nothing more was done till

Oct. 21, when the tendon of the *m. tibialis anticus* was divided two inches above the ankle-joint, with a *phimosis*-knife, and snapped with a sharp report. Motion was immediately restored, and the sole could be placed on the ground, but returned to its old position when left alone, and she then suffered great pain in the instep, and up the front of the leg, which continued for three hours. It therefore was necessary to preserve the natural position, by applying a foot-board to the sole, on the sides of which the branches of a stirrup were attached, and from its crown a rod, with a screw for adjusting its length, was carried upon the front of the leg, and fixed by a circular bandage below the knee. This apparatus did not answer the purpose, and therefore, on the following day, I put Boyer's splint on the outside of the limb with a foot-piece. This was continued for more than a week, but every day the foot was found returned to its old posture, and for the greater part of the time the pain in the leg continued. At the end of the week a back-splint was put behind the length of the limb, and the top of the long splint fastened to it, to prevent it turning forward, in which position it had been daily found. This at first seemed to do very well, but it failed, though carefully attended to in the same way for a fortnight.

Nov. 15. Still nearly as great inversion of the foot as at first, but it could be restored to its proper place by the hand as easily as at first, and when let go again became distorted. The peroneal muscles do not seem to have the least power. Flexion of the foot upon the leg is much restricted, and it seems probable that the ACHILLES' tendon will require division.

Wishing to try whether any advantage would be attained by her attempting to walk, an apparatus was applied on the outside of the leg, consisting of an iron rod, jointed at the ankle and keee, and extending half up the thigh, with some straps round the leg and thigh, and a foot-piece at right angle with its lower end, upon which the sole of the foot was firmly bound with a roller. She was directed to move about with this, and upon crutches. The sole bears well on the ground, but the great toe turns inwards, and she has pain along the back of the leg. This plan was persevered in for ten days, the bandages being adjusted as was found necessary.

Nov. 25. On consultation with DR. LITTLE he thought the *m. tibialis posticus* was at fault, and I therefore divided it with a *phimosis*-knife, from behind forwards—to wit, entering the knife between the tibial and long flexor muscles of the toes, about three inches above the ankle, and carrying the point down to the bone, cutting with it inwards. The inversion immediately subsided, and the foot recovered its natural position; a slip of plaster and a narrow roller were applied, but nothing more done.

In the evening she had pain along the inside of the shin-bone, which increased during the night, and subsided on the following morning, but came on again towards evening with severe burning, and a sensation of stretching along the front of the leg, but which entirely subsided next day.

Nov. 29. On visiting her this morning, the foot was again found a little turned in the old direction, which she herself had noticed when she first woke this morning. She complains of "a shrinking pain along the inside of the leg, very different from the stretching which she first felt on the night of the 26th; but which has now entirely ceased.'' The foot can be restored to its natural position without the least difficulty, but, when left alone, has still the disposition to turn in. The jointed iron rod and foot-piece were therefore reapplied, and answered well.

From this recurrence of the distortion, and the continued absence of the menstrual discharge, accompanied with headache and pain in the loins, it became questionable whether it might not really be an hysterical affection, of which indeed there had been a suspicion when she was first admitted. It was therefore determined that she should take *mist. ferri. comp.* ℥jss. *ter die*, which was continued till

Dec. 16 without any benefit. It was therefore left off, and five grains of ergot of rye three times a day, with a warm foot-bath every night, were ordered. Two days after, the headache and pains in the loin were much relieved, and had ceased entirely on

Dec. 23; but no change or improvement has occurred as to the menses, or the inversion. The medicine was suspended for three weeks.

Jan. 28, 1838. The ergot resumed for a week.

Feb. 7. The ergot again. Ordered for the same period.

Feb. 24. No alteration. The foot continues turned in, but there is no disposition of elevation of the heel. It was therefore determined to excite the action of the *m. peronei* by blistering along their whole length.

March 3. A second blister has been applied, but there is no improvement; indeed, the heel is more elevated. A third blister was then put on, and the stirrup readjusted to the foot and leg. On the following day the menstrual discharge appeared sparingly, the first time for thirteen months, and continued only a couple of days.

March 31. She took a dose of the ergot, and next day the menses appeared, and continued for three days; but no recovery of the foot followed, and she left the house in

April, with the sole still turned inwards and upwards.

I saw nothing of her for several months, till I accidentally met her; and, observing she was walking well with the sole of the foot to the ground, which she informed me had recovered itself, without any further treatment, a month or two after she had left the house, and that she was menstruating regularly.

From this account, I was led to believe that the contraction of the muscles, which had successively occurred, was hysterical, and that the operations I had performed were superfluous.

Varus sometimes occurs as consequence of palsy of the muscles of the leg during teething. I operated, in 1839, on a case of this kind in a girl, between eleven and twelve years old, in which the foot first dangled from the ankle; but, as she grew up, and began to walk, inversion commenced, and, when I first saw her, whilst standing upright, the foot rested on the whole *dorsum pedis*, except the great metatarsal bone, which faced outwards; the tuberosity of the heel-bone was raised about an inch from the ground, and its under surface faced inwards; before this bone nearly the whole sole faced directly upwards. When lifted from the ground, the foot nearly recovered the natural position; but there was still a little disposition to inversion, and the weight of the front of the foot pointed the toes. When the knee was straight, the foot could not be flexed at all on the leg; but, when the knee was much bent, the sole could be almost entirely applied to the ground. The gastrocnemial muscles were little developed, and the muscles generally did not control the foot. The ACHILLES' tendon was divided, and extension made; after five weeks, a steel rod, jointed at the angle and knee, and attached to a boot, was put on, soon after which she got up, and, in rather more than seven weeks, began to walk with the sole flat on the ground, with the assistance of a stick, which, in the following week, she threw aside of her own accord, and walked slowly without assistance. She would probably have improved more quickly, but that a slough formed on the skin of the tuberosity of the heel, in consequence of the foot-piece of the first-applied apparatus having pressed unduly. At the end of six months she walked very well, and the treatment had perfectly succeeded.

Shortly after, I had another case of the same kind in both feet of a child, three years old, in which the same proceeding was adopted with success, as the child walked upon the soles tolerably at the end of six months, whilst wearing boots with jointed steel leg-rods. But he could not do without these, as the paralytic muscles had not recovered, although galvanism had been employed.—J. F. S.]

1373. As to the *prognosis* of this ailment, all depends on its degree and complication. If there be simply disproportion between the muscles, if the twisted bones have neither their form changed, nor are fixed in their unnatural position by *anchylosis*, a favourable issue may be hoped for; and the more if the patient be young, far distant from manhood, have no accompanying dyscrasic disease, and the nutrition of the curved foot have not suffered much. The time in which the cure of this ailment may occur, is not determinable, and depends upon the mode of its treatment, in addition to its degree and duration. In adults who have walked long on their crooked feet, in which the bones are anchylosed, or considerably changed in form, their complete cure is impossible.

1374. The *treatment* of club-foot consists in the restoration of the natural antagonism of the muscles, and of the straight direction of the foot, which is effected either by lengthening the shortened muscles by means of gradual extension and mechanical contrivance, or by cutting through the tendons of the shortened muscles, and subsequently straightening the foot by mechanical means. The first (mechanical) mode of treatment is always tedious and difficult, especially in a greater degree and longer duration of club-foot, in which case frequently it is of no service. It is indicated in slighter degrees of club-foot, when the foot can, without much trouble, be brought straight, and a constant careful oversight of the patient is possible. The division of the tendons is in all cases the most fitting, when the first mode of treatment has been without benefit, or where the greater degree and duration of the curvature has led to the expectation of its being baffled, or, from external circumstances, a speedy termination of the cure is required.

1375. The treatment, by gradually lengthening the shortened muscles, is divided into the periods of *rightly directing*, of *steadying the foot*, and of *walking*.

In order to bring the foot gradually into the straight direction, it is recommended to use a warm bath, in which twice daily, the foot is to be immersed up to the knee, for about half an hour, and during this time attempts made to bring the foot into its natural position, holding it with one hand, so that the thumb lies upon the back, the forefinger on the inner edge, and the other fingers upon the sole of the foot, and with the other hand placed round the heel, by which the foot, and especially the heel, is turned outwards, the front of the foot raised, and its hind part depressed. These manipulations must be carried on slowly, and for some time. When the foot has been taken out of the bath, and properly dried, lard or goose-fat is to be rubbed on the inner and hinder part of the leg, and on the inner and *plantar* surface of the foot, and any spiritous fluid should be rubbed on the fore and outer part of the leg and foot. For the purpose of keeping the foot drawn towards its natural direction, a triangular piece of cloth is used, folded to the breadth of two fingers, and about three-quarters of an ell long; it should be placed beneath the calf, carried around both ankles, from without inwards, over the back, and over the middle of the inner edge of the foot, under the sole outwards, and, by proper drawing, it bends the foot outwards. This turn being repeated, the tip of the cloth is carried from the outer, obliquely upwards towards the upper edge of the foot, and both then connected by a packer's knot upon the back of the foot, are carried around the ankle, and tied together (BRÜCHNER's bandage.) This cloth must be applied once or twice a day; but, as it nevertheless is easily displaced, strips of sticking plaster may be applied on the same plan, much more efficiently, for the purpose of bringing the foot into place (*a*).

In children born with club-foot, we are restricted for the first two or three months, on account of the delicacy of their skin, to frequent daily manipulation, by which it must be attempted to bring the foot gradually to its place; and subsequently the mode of treatment proposed is to be employed. Success is frequent in these cases, on account of the slight degree of the evil and the yieldingness of all the parts. A club-footed patient who has already walked, must from the very onset of the cure be carefully restricted therefrom.

SCARPA has recommended a peculiar spring for gradually bending the foot outwards; it is applied on the outside of the foot, and fastened with two straps. Repeated experience has decided me on giving up this practice, and giving preference to the sticking plaster.

[As far as I have had opportunity of observing, little real benefit is derived beyond straightening the foot, whatever bandage or apparatus be used, before the child can be put on his feet, and the weight of his body counteract the unnatural contraction, or disposition to contract, of the gastrocnemial muscles. I therefore rarely do more than, as CHELIUS recommends, fix the foot with sticking plaster, and, perhaps, put on a light tin shoe, with a back, to render the bandage more firm, but with little expectation of flexing the foot.—J. F. S.]

1376. When the foot has been so far managed, that it can be brought with the hand to its proper place, it is best retained there by the so-called SCARPA's second machine (1), which is applied over the stocking and worn day and night. The patient may then be permitted, gradually and upon even ground, to stand and walk. After some time, when the foot retains of itself its natural position, the apparatus may be left off during the day, but still worn at night. It is best to let the patient wear a laced boot, which should lace to the toes and have a thin steel plate at its back.

(1) SCARPA's machine consists of a shoe, the front of which is made of a thin padded shoe sole, and the back part of a steel plate (a parabolic spring) which encloses the

---

(*a*) GIESE. Salzb., Medic.-Chirur. Zeitung, 1814. vol. iv. p. 75.

whole heel. On the inner part of this parabolic spring is a padded strap, which is drawn over the back of the foot and fastened to a stud on its outside. A horizontal spring is continued from the outside of the parabolic one to the tip of the foot, around which it is fastened by a padded strap. At the hind end of this spring is a strap fastened to a stud on the inside of the parabolic one; and from the outside of the latter a moderately curved spring, with its concave surface towards the leg, ascends up to the region of the knee, and is connected with the parabolic spring by a rivet in form of a T. Two padded straps serve for fastening it to the leg above the ankle and below the knee, which, by means of pieces of tin and screws, can be variously attached to the vertical spring. Scarpa's machine is similar to that proposed by Delpech (*a*). To it must be given merited praise and preference above all others (*b*) (2).

Besides those mentioned, a number of machines and apparatus have been proposed, of which mention can only be made. Hippocrates' laced boot; the apparatus of Paré, Hildanus, and Haar; the machines of Venel Brünninghausen (*c*), of Autenrieth, of Blömer (*d*), of Delacroix, and others.

[(2) Scarpa's shoe is a very good instrument when the *varus* is not great, but it will effect no benefit in a bad case; nor will any other; and division of the tendon, or tendons, will be requisite to produce a cure. I may mention, that where I have seen it used, the child walks on his heels, and in spite of the spring, the gait is that which is so well known as resulting from what is called *pigeon toe*.—J. F. S.]

1377. The subcutaneous division of the tendons for the more speedy restoration of the position of the foot especially applies to the Achilles' tendon, the tendon of the *m. tibialis anticus*, and the plantar *fascia*. The Achilles' tendon generally offers the greatest hindrance to the proper direction of the foot; its division alone is in many cases sufficient, or only in the after-treatment is the necessity for the division of the other tendons declared; often, however, on first examination the necessity for the simultaneous division of both is shown by the great stretching which the other tendons present. Besides those mentioned, I have, even in the most severe degree of club-foot, never found it necessary to divide any other, although the division of the tendons of the *m. tibialis posticus* and of the *m. flexor longus pollicis* have been considered necessary and performed by others; and Stromeyer, who has frequently cut through the tendon of the *m. tibialis posticus*, himself admits that from the result of his observations on the division of this tendon no decisive influence upon the restoration of the form and function of club-foot is to be ascribed to it.

1378. The division of the Achilles' tendon is performed most simply and effectually in the following manner. The patient is laid upon his belly, the leg held by one assistant and the foot pressed in its natural direction by another, so that the Achilles' tendon may be tightly strained and very prominent; the thumb and forefinger of the left hand are then to be placed on both sides of the tendon to fix it and the skin covering it, and then a narrow *slightly* convex and pointed bistoury (1), held flat, is to be thrust in at the inner side of the tendon and directly behind it, about two inches above the heel, beneath the skin, without penetrating it on the outer side, and then the edge of the knife being turned towards the tendon, cuts it through (whilst the flat of the thumb of the left hand placed upon the tendon presses it against the edge) with one or more strokes, without injuring the skin. At the moment of the complete division of the tendon a crack is heard, the two ends of the tendon separate more or less widely asunder, and the foot inclines in the same proportion to its natural position. As soon as the knife is withdrawn slight pressure

(*d*) B. Bruns, Dissert. de talipede varo. Berol., 1827.

should be made with the thumb against the little wound, to squeeze out the blood and to prevent the entrance of air; the wound is to be covered with some strips of sticking plaster and wadding, which are fastened with some turns of a lightly-applied roller. The patient is then to be carried to bed, and the foot placed in a suitable position.

Thilenius (*a*), Michaelis (*b*), and Sartorius (*c*) cut through the tendon simultaneously with the skin. Delpech thrust the blade of a bistoury behind the Achilles' tendon, so that on both sides a skin wound is produced about an inch long; a convex knife is then introduced, with the edge of which towards the tendon he divides it transversely, without wounding the skin above it. Stromeyer thrusts in a narrow curved fistula-knife about two inches above the heel, behind the Achilles' tendon, and out at the other side, and cuts through it in withdrawing the knife. Stoëss makes with a narrow double-edged bistoury, which he thrusts in flat behind the Achilles' tendon, a wound two and a half inches wide, without perforating the skin on the other side, draws the bistoury back, and introducing a button-ended one, slightly curved, and cutting on to a slight extent, with which he divides the tendon. Bouvier (*d*) makes a slight puncture in the skin with the point of a lancet a few lines before the tendon, where it is thinnest and strongest, and introduces through this puncture a straight narrow button-ended tenotome between the skin and tendon, and cuts through from before backwards. Guérin brings his narrow tenotome, slightly rounded in front, through a previously made small skin-wound beneath the tendon. Scoutetten stretches the skin with the fingers of the left hand, at the same time drawing it somewhat inwards, and thrusts in the tenotome at the inner side of the tendon, carrying it from behind forwards and from within outwards, without penetrating the skin on the opposite side; he now depresses the handle, draws the knife backwards and forwards, and the tendon is divided. Dieffenbach and others practise in the above-mentioned way.

[(1) I never use any other than a common *phimosis*-knife, which I pass flat *before* the tendon, till I can feel its point against, but without penetrating the skin on the outside of the leg; then turn the edge to the tendon, which being made tense by an assistant, and pressed against the knife with the left thumb, I cut through with the end of the knife as I withdraw it.—J. F. S.]

1379. When after from three to five days the little wound has closed, the return of the foot to its natural position is to be set about with a machine, which gradually effects the necessary apparent change of position. Stoëss' apparatus best answers this purpose. The return of the foot to its natural place ensues more quickly or more slowly according to the degree and duration of the curvature; all violence must be avoided, and by the *gradual* reinforced degree of extending the foot and proper soft pads, all painful pressure and excoriation are to be avoided. When the foot is brought to its natural position, Scarpa's apparatus may be applied and the patient allowed to walk. The movements of the foot are at first uncertain and stiff, but they improve by exercise, and in similar proportion does the atrophic condition of the muscles diminish, to which end rubbing at the same time with spirits may somewhat contribute.

Delpech's apparatus (*e*), Stromeyer's (*f*), Scoutetten's (*g*), and Pauli's (*h*) are also used for this purpose. Pauli, when after two or three days the little wound is healed, surrounds the foot with a mould of plaster of Paris, which he makes in a sort of jointed wooden boot and leaves to harden. If the proper position of the foot cannot be at once effected, he renews it frequently (1).

In not very great curvature, the foot often at once, after the division of the Achilles' tendon, can be restored to its natural position, and in these cases the extending machine may be at once applied. In most cases, however, this is impossible, or pain, inflam-

mation, and so on, are too easily excited by the extending force; it is therefore best to commence the setting straight first when the little wound has healed, (**Stromeyer**, **Dieffenbach**, **Stoëss**, myself, and others,) (2), and not immediately after the operation (**Thilenius**, **Michaelis**, **Sartorius**, **Delpech**, **Bouvier**, **Pauli**, **Duval**, **Blasius**.)

[(1) When I first began to operate on cases of *varus*, I had not any opportunity of either being acquainted with or seeing **Stromeyer**'s apparatus, which I think is by far the best instrument for treating these cases I know of, and I used **Boyer**'s splint for fractured thigh, with the shoe, which I first fastened on the foot, and then having fixed it upon the projecting bar, gradually, from day to day, drew down the upper end of the splint to the plane of the thigh-bone as the patient could bear it; for although when the shoe was firmly fixed, the length of the splint was so great, that it produced such powerful leverage as to overcome every resistance to placing the foot immediately in its proper position, yet I was afraid of attempting it at once, on account of the violence which would have been needed, and the pain the patient would have suffered; for even in the way I used it, the patient suffered considerably from the stress of the shoe-straps, and constantly sought to relieve himself, so that almost daily the foot was found more or less displaced, however well it had been arranged on the previous day, and therefore the progress of the cure retarded.

I therefore altered my plan, and instead of at once attempting to turn the sole down and flex the leg upon the foot, I first endeavoured to get the foot straight with the leg, leaving the toe pointed, and the heel raised, or in other words, to convert the club-foot into horse-foot, and afterwards gradually to flex the foot on the leg from day to day. The first part of the proceeding was effected by **Boyer**'s splint and shoe, with the simple alteration of making the foot-bar, upon which the shoe was fixed, round instead of square, so that when the bar was entered into its socket, the sole of the foot was readily turned down without making any flexion upon the leg, the socket moving on the bar as the toe pointed, which it is always first disposed to do after the division of the **Achilles**' tendon. After a few days, when the patient had become accustomed to this new position, I began gradually to flex the foot on the leg, by slipping the foot-piece into the foot-piece of the stirrup apparatus for fractured knee-cap, the circular bandage of which was fixed above the knee, and then gradually shortened the screw rod as the patient could bear the stress upon the ball of the great toe, which was considerable. This answered the purpose, but it was a very clumsy contrivance, and I soon managed to contrive a more simple and efficacious instrument, which consisted of a pair of long narrow splints, like **Boyer**'s splint, one for the outside, and the other for the inside of the leg and thigh, which were connected at bottom by the circular bar on which the foot-piece moved, and upon the leg and thigh, by three or four straps and buckles. For flexing the foot, a stud was placed on each edge of the foot-piece, near its toe end, upon each of which a leather strap fastened, by which the toe end of the foot-piece could be drawn up, and the foot flexed on the leg, to such extent as might be wished; and this being determined, the other end of each strap was fastened on a stud in the side of the corresponding splint upon the thigh.

This apparatus I have used very frequently and successfully, and with children it serves every purpose required, if the Surgeon be content to restore the straight position of the foot first, and afterwards to flex it. The instrument has the advantage of being easily made by a common carpenter and smith, and with little expense, even if a new one be made for every case treated. I do not presume to put in it competition with **Stromeyer**'s excellent apparatus, which cannot always be obtained when required, is expensive, and needs some little practice for its proper employment. It is, however, a most capital instrument, and effects at the same time the flattening of the sole and the flexion of the foot with little more than a feeling of confinement to the patient, if it be properly adjusted.

(2) I fully agree with those who prefer leaving the limb at rest for a few days after dividing the tendon; as the patient then bears the extension with less pain. I first began by putting the limb in place at once after the operation, but finding it often necessary to slacken the bandages, I gave it up, and pursued the other practice with greater satisfaction.—J. F. S.]

1380. If there be present with club-foot, considerable bending of the toes and great concavity of the sole of the foot, in which case the plantar *fascia* is stretched like a cord in attempting to extend the foot, the division of that *fascia* is necessary (1). If the foot be strongly drawn inwards, and the curving of its outer edge be so considerable that the great toe and the inner edge of the foot are much contracted, then the tendons of the *m. tibialis anticus* and *extensor proprius pollicis* must be divided. In greater bending inwards of the foot, so that it can only with the greatest force be moved towards the horizontal axis of the shin-bone, the tendons of the *m. tibialis posticus* and *extensor proprius pollicis* must be cut through.

In dividing the plantar *fascia*, the heel and toes should be strongly drawn asunder by an assistant, by which the *fascia* is still more stretched and projected, the knife is to be introduced, flat, on the inner edge of the foot under the *fascia*, its edge should then be turned and the *fascia* cut through as it is withdrawn, without injuring the skin on the opposite side, which I have often done with ease. The tendon of the *m. tibialis anticus* may in this way be divided at the lower end of the shin-bone, where it projects very greatly beneath the skin; also the tendon of the *m. extensor pollicis proprius*, to the outer side of which the anterior tibial artery lies, and may be easily avoided. The division of the tendon of the *m. tibialis posticus* is made half an inch above the inner ankle; the nail of the left forefinger is to be placed over the posterior tibial artery, and the point of a curved knife carried to the bone, and forwards upon it, divides the tendon (2). A cut three-fourths of an inch long is made more conveniently along the course of the tendon above the inner ankle; the foot is then turned outwards, and the exposed tendon divided with the point of a knife (STROMEYER.) The tendon of the *m. flexor pollicis longus* is cut through near the inner edge of foot, where, when violently stretched, it projects between those of the *m. flexor pollicis brevis* and of the *m. adductor pollicis*, beneath the skin, without thrusting the knife out at the other side.

[(1) Shortening of the inner portion of the plantar *fascia*, producing great diminution in the length, with considerable elevation of the inside of the arch of the foot, in which case, the great toe generally stands almost upright, instead of resting horizontally on the ground, I have seen several times, independent of any disposition to club-foot. I have usually cured it without difficulty, by thrusting a *phimosis*-knife on the inside of the foot, opposite the base of the great metatarsal bone, between the skin and *fascia*, and dividing the latter in withdrawing the knife. No apparatus is requisite, but after three or four days, when the weight of the body can be borne, the patient is to be directed to walk about a little, so that the the newly-formed connecting matter is gradually lengthened, and the arch of the foot drops to its natural level; the great toe also at the same time recovers its place.

(2) The division of the tendon of the *m. tibialis posticus* is the only one which requires much anatomical knowledge or care, on account of the close neighbourhood of the posterior tibial artery, which I once divided in performing this operation on a child; it bled very smartly for a few minutes, and having enlarged the wound, I attempted to take it up, but the ends had retracted so much, that I could not succeed. and therefore thought best to bring the edges of the wound together and apply a compress. Union took place, and no hæmorrhage occurred. I have been told that such accidents are not very unfrequent, and that no inconvenience follows; but there can be no doubt it were better avoided.—J. F. S.]

1381. If the patient be kept quiet, ordinarily no important symptoms come on; I have not, at least, observed any in my own practice; and if they occur, they would depend rather on the patient's constitution than on the operation itself, if properly conducted. Should inflammation ensue, and if it be not dispersed by cold applications, the *pus* must be early evacuated, and by proper treatment the extension of the suppuration and exfoliation of the tendon prevented. If unfavourable symptoms occur after this operation, and if in some cases of old and very considerably curved club-foot the result of this operation be not perfect, or even not considerable, and which indeed cannot be previously ensured, yet they do not damage the value of this operation. Even in the earliest childhood it may be employed.

Blasius supposes that the operation, when applied to true club-foot, that is, to severe cases, where it alone can be preferred, effects little or nothing; that it rather only applies to spurious club-foot, and especially to slight cases. Club-foot is a complication of anomalies: and that the inversion is the most important point; but the operation is directed against only one anomaly, and not at once against the most important. Many groups of muscles participate in the vicious position; the operation is only directed against the muscles of the calf,—at most against the *m. tibialis anticus* or some one of the others. Atrophy of the leg is always present, and against it can the operation be of no use. This opinion is contradicted by what has been already said, and by the experience both of others and myself. Against **Blasius**'s opinion of the propriety of amputation in such states of club-foot, compare **Stromeyer** (*a*).

---

b.—OF SPLAY-FOOT.

(*Valgus*, Lat.; *Plattfuss*, Germ.; *Pied-plat*, Fr.)

Buchetmann, Inaug. Abh. über die Plattfuss. Erlangen, 1830; with plates.

Nevermann, Ueber den Plattfuss und seine Heilung; with a plate; in Hamburger Zeitschrift, vol. iv. part ii. 1837.

Stromeyer, above cited, p. 99.

Dieffenbach, above cited, p. 127.

1382. *Splay-foot*, the reverse of club-foot, is a frequently occurring deformity, in which there is not any actual twisting, but rather only such inclination of the foot outwards that the inner ankle projects very much and descends lower than natural, that beneath the outer ankle is a more or less deep depression, the natural arching of the back of the foot and the cavity of the sole and of the inner edge of the sole are lost, and the foot touches the ground at once with the whole sole, and is widest at the *tarsus*. Generally the foot is unusually cold, dusky red or bluish, as if frost-bitten, but, however, much disposed to sweat, so that it is always moist; the skin of the sole is soft, and without the usual hardness and callosities. In walking, splay-footed persons direct the knee inwards and the foot outwards, so that they mostly tread on the inside of the foot.

1383. The inconveniences in splay-foot are, speedy fatigue in walking, swelling of the foot around the ankles, and soreness of the soles of the feet, on which account persons so affected are not fit for military service in the infantry. From the continual straining of the feet, even chronic inflammation of the ligaments and synovial membranes arises, by which not merely pain but also serous exudation among the tarsal bones takes place. This requires rest, by which the transition to *caries* is prevented (**Stromeyer.**) It is remarkable that affections of all kinds arising on the feet or legs of splay-footed persons, especially inflammations and ulcers, are always remarkably stubborn.

Splay-foot must be distinguished from *Broad*-foot, which is simply an enlargement of the natural form of the foot dependent on the extension of the lateral ligaments, attached to the metatarsal bones, caused by their frequent use (*b*).

(*a*) **Casper**'s Wochenschrift, 1836. Nos. 34, 35.

(*b*) The Circular to the Prussian military physicians, showing the difference of Broad and Splay-foot, in reference to the examination of recruits; in **Rust**'s Magazin, vol. v. p. 1.

1384. Splay-foot is either congenital, and shows itself in different degrees directly after birth, as I have several times noticed, in which there is unyieldingness of the *m. peronei*, especially of the *m. peroneus longus*, and the ailment is certainly caused by the position of the child in the womb; or it is developed later, rarely in the female sex and in children under ten years. There is probably a congenital disposition in the position of the tarsal bones, or atony of the plantar *fascia* and tarsal ligaments, where first, at a subsequent period, and from straining in standing, walking, and so on, splay-foot is developed, and the heel-bone is so twisted inwards that its outer surface inclines more upwards, and the inner more downwards at the same time. The position of the other tarsal bones and their joints is little changed; the head of the *astragalus* and cuboid bone often project rather more inwards. In many families, especially among Jews, splay-foot is hereditary. Continual standing, especially with bare feet upon the damp ground, and much work influence its development. In the higher classes splay-foot very rarely occurs.

As to the causes of splay-foot, which have, however, only recently been attentively noticed, opinions are different. According to Liston (*a*) the ailment arises from a thickening (*exostosis*) of the distal end of the first metatarsal-bone, in consequence of blows, rheumatism, gout, and scrofula, in opposition to which Froriep (*b*) correctly observes, that this is only an accidental complication of splay-foot. Rognetta (*c*) holds congenital splay-foot consequent on deficient development of the heel-bone, and the acquired, as consequence of relaxation of the ligaments of the tarsal bones. Thune (*d*) lays the cause in a twisting round of the heel-bone, so that its outer surface is turned upwards, and its inner one somewhat inwards. The firm connexion between the heel-bone and *astragalus* by their unyielding ligamentous apparatus, causes a similar change in the position of the *astragalus*. If deformity be added, it is accompanied with subluxation between the articular surfaces of the head of the *astragalus* and the navicular bone, in which case the tuberosity of the latter sinks lower than the front part of the head of the former, which is itself sunken. The ligaments, especially the dorsal ligaments, between the *astragalus* and navicular bone, but still more, the plantar ligaments, and most of all, those between the two bones are very much stretched. The front fibres of the deltoid ligament, and *ligamentum fibulare tali anticum*, are also considerably stretched, as the shin-bone rests only on the hindermost part of the upper joint-surface of the *astragalus*, and thereby the navicular bone is removed more forwards and the splint bone more outwards from the navicular bone. Stromeyer places the cause of splay-foot in atony of the plantar *fascia* and of the tarsal ligaments. As these yield to pressure, the foot loses its arch, and contrariwise inclines outwards, because the action of the tibial muscles and of those of the calf, which properly press the outer edge of the foot and the ball of the great toe against the ground, in less strength of the ankle-joint, urge the shin-bone inward, which at the same time is accompanied with a driving forwards of the same bone. Atony of the leg is not to be considered as one of the causes in splay-foot; for in some degree of bad cases all the muscles are in such stretched condition that it cannot be ascribed to atony.

Thune (*e*) distinguishes *primitive* and *secondary valgus*. The former is already fully developed at birth, and accompanied with a stretching of the muscles on the fore and outer part of the leg, which increases and becomes painful if it be attempted to put the foot straight; but the foot itself is not deformed. *Secondary valgus* occurs long after birth, after the patient has been accustomed to walk, and is constantly accompanied with a change in the form of the foot. Thune has endeavoured to ground this distinction on the different appearances in the one or other form. In *secondary valgus* the axis of the foot is on its outer edge, concave externally. The inner ankle and the navicular bone form a projection, which, in walking, always more nearly approaches the sole, so that the *valgus* is in the highest degree *talipes*; the heel and the outer edge of the foot are away from the ground; the Achilles' tendon lies concealed behind the fold of skin, and is felt removed somewhat to the outer side; the heel is drawn upwards; the outer *malleolus* lies concealed in the ankle-joint; the leg, in consequence of wasting, is equally

---

(*a*) Lancet, March, 1835.

(*b*) Chirurg. Kupfert. pl. 339.

(*c*) Archives générales de Médecine, 1834.

(*d*) Nevermann, above cited.

(*e*) Nevermann, above cited.

thick below and above, so that the knee appears as if deformed; the back of the foot (instep) is very much arched; and walking is performed generally not with bended knees. In splay-foot the axis of the foot is not changed, the ankle is very prominent, is lower than usual, and touches the ground; the whole sole of the foot touches the earth; below the outer ankle a cavity is formed, the depth of which depends on the degree of the deformity; the heel cannot be drawn up; the outer ankle is distinctly felt; the muscles of the calf are not greatly wasted; the back of the foot is not properly arched, but has at the *tarsus* an unnatural flattening and breadth; walking is generally performed with the knees bent. This distinction, however, depends on no actual difference, but is only consequent on simultaneous contraction of the muscles, that is, those of the calf, and on shortening of the **Achilles'** tendon; therefore, in such cases, the division of that tendon may be sufficient (*a*).

1385. In slighter degrees of splay-foot, and in young persons, the foot may be rubbed twice a-day with spirituous fluids, then wrapped up in a bandage, moistened with spirits of wine; cold baths are to be taken from time to time, or a laced leather stocking worn, which equally encloses the foot and leg, and a shoe, with a strong tin plate, which is convex from behind forwards to the metatarsal bones. According to **Dupuytren**, a shoe, with a flexible elastic sole, and raised in height from half to three-quarters of an inch; according to **Rognetta**, a raised shoe, together with swathing the foot in a bandage moistened with camphorated spirit, which is to be looked to and tightened twice a-day; according to **Stromeyer**, a boot, in the middle of which a piece of leather is fastened, confining the middle of the foot from below, upwards, and from within, outwards, then runs pointed, and is fastened by a slit in the upper leather at the outside of the foot, to a buckle. In weakly persons an internal strengthening treatment is at the same time proper. In old persons, and in a high degree of splay-foot, exutories are to be kept long to the sole of the foot, blisters upon its inner edge and on one part of the sole, and suppuration kept up by acrid ointment, for the protection of the foot-swathing, and a laced boot (**Stromeyer**.)

Liston recommends a plaster of mercury and iodine to the swelling of the front end of the first metatarsal bone, and if this be insufficient, the head of the bone is to be removed with cutting forceps.

If the splay-foot be great and dependent on diseased contraction of the muscles, against which mechanical assistance is fruitless, **Held** (*b*) proposes dividing the *m. peronei* and indeed the tendons of the *longus* and *medius*. The *peronei* contained in a common sheath are most prominent from four to six lines above the outer ankle; a double-edged bistoury is to be introduced flat beneath them from behind forwards, and the edge turned against them. The tendon of the *m. peroneus medius* has here still some muscular fibres. The tendons of these muscles are enclosed in proper sheaths from four to six lines under or before the ankle, but they lie so close together that they can be divided at the same time, as the knife is introduced between them and the heel-bone, from above downwards, and somewhat from before, backwards. The tendons of the *m. peroneus medius* may be divided also four or five lines from the base of the fifth metatarsal bone.

[In the cases of splay-foot which I have seen, the cause of the mischief appears to have been principally in the inner plantar, or calcaneo-navicular ligament; and it is generally accompanied with tenderness in this neighbourhood. I have usually directed repeated leeching till all tenderness had subsided, and perfect rest; but the relief has only been temporary.—J. F. S.]

(*a*) **Stromeyer's** case, above cited, p. 95.

(*b*) Above cited, p. 63.

c.—OF HORSE-FOOT.

(*Pes equinus*, Lat.; *Pferdefuss*, *Spitzfuss*, Germ.; *Pied équin*, Fr.)

Jörg, Ueber die Verkrummungen, p. 77.

Zimmerman, Der Klumpfuss und Pferdefuss. Leipzig, 1830.

Dieffenbach, **Bonnet**, and **Phillips**, above cited.

1386. *Horse-foot* is that malformation in which the whole splay-foot has one and the same direction with the leg; the heel is considerably drawn up, so that in walking the patient only treads with his toes, and especially with the ball of the great toe. The **Achilles'** tendon is very tense, the foot at the same time so arched that the convexity of the back and the concavity of the sole are increased. In the greatest degree so complete a turning about of the foot may be produced, that the tip of the foot is turned backwards, and the patient walks entirely on the instep (*a*).

1387. The cause of this ailment lies in an unnatural contraction of the muscles of the calf; subsequently also the *m. plantaris* and plantar *fascia*, the *m. tibialis posticus* and *peroneus longus* shorten, and the curvature is increased. In a very high degree of this ailment the joint surfaces of the *astragalus* are so far pushed forward, that they are nearly out of contact with the shin-bone, which rests almost entirely upon the back part of the heel-bone; however, it is frequently observed that in long continued and severe horse-foot, the tarsal joints are not particularly changed, but that there is a considerable removal of the front ends of the metatarsal bones from their connexion with the toes, inasmuch as they bear the chief weight in walking, in consequence of the toes being so much turned upwards.

Horse-foot is congenital or acquired; the latter is most common, because, if at the time when the **Achilles'** tendon is shortened the ankle-joint have not yet attained sufficient firmness, partly from the deficient development of the ligaments, partly from that of the ankles, and especially of the inner, club-foot is quickly produced by the simultaneous shortening of the *m. tibialis anticus* and *posticus*. Some inclination of the foot inwards is, however, frequently observed in horse-foot. Diseased change in the tarsal bones may also give rise to similar displacement.

1388. In reference to the causes, all that has been said in general, and on club-foot, applies here (1).

The *treatment* consists in the employment of baths, relaxing rubbings of the contracted muscles of the calf and their tendons, in manipulations, for the purpose of bringing down the heel and raising the front of the foot, which position must be maintained by the apparatus of **Jörg** (*b*), **Stromeyer**, **Stoess**, and others. In a great degree and long continuance of horse-foot, no perfect cure is effected by this treatment, even though it be long persisted in; and the only division of the **Achilles'** tendon and the subsequent application of proper apparatus, as in club-foot, in a short time can restore the straight position of the foot. If the back of the foot (instep) be very much arched and the plantar *fascia* stretched like a cord, its division is mostly necessary. **Stromeyer** also cut through, in some cases, the tendons of the *m. flexor longus* and *extensor pollicis*, on account of a permanent improper position of the great toe.

(*a*) **Stolz**, Mémoire sur une variété particulière du Pied-bot; in the Journal de la Société des Sciences de Basklim. Strasbourg, 1826, vol. iii. p. 458.

(*b*) Above cited, pl. vi.

Jörg's apparatus consists of a shoe like that of Scarpa's for club-foot; on the outer side of which an iron rod ascends to the knee and is fastened round the leg with a strap. At the lower part of this rod is a spring furnished with a stop-wheel, to which an iron rod is attached, which runs forwards along the foot. A strap carried round the front of the foot is affixed to the end of this rod, by which the foot is always drawn up (2).

[(1) Among the causes which produce permanent contraction of the gastrocnemial muscles and consequent horse-foot, may be enumerated ulceration, of which I had a good case in 1837, in a strumous girl, whose heel was raised four inches from the ground, the muscles being much shrunk in the calf, and the scar of the skin closely connected with them. The motions of both knee and ankle being perfectly free when the knee was bent, I divided the Achilles' tendon, and she was cured completely.

I had also, in the same year, a case of horse-foot under my care, which followed a palsy of the left arm and leg during teething, first at ten months, and next at two years of age, from which, however, when three years old, the patient had recovered so far as to walk about with the aid of a stick or crutch; and when about sixteen, he was able sometimes to walk even without a stick. Towards the end of the following year the heel began to leave the ground, and slowly rose still higher till he was twenty years old, when it was at least four inches from the ground, and had so continued when I saw him a twelvemonth after, (*Sept.* 1837,) the *tarsus* and *metatarsus* being then on the same plane as the front of the leg, and the foot resting only on the ball of the great toe. The foot was livid and pappy, and when lifted off the ground, dangled at the ankle-joint, both flexor and extensor muscles appearing to be paralysed. Although, under these circumstances, relief from division of the Achilles' tendon seemed to be very doubtful, I thought it worth while performing the operation, so that the sole might be brought to the ground, and then that attempts might be made to excite the muscles on the front of the leg to action. The tendon was therefore divided in the usual manner on *Sept.* 30, which brought the sole again flat, and its position was preserved by the stirrup and rod attached to a circular knee-strap, and the foot was gradually more flexed by shortening the rod as he could bear it. After wearing this apparatus six weeks, the foot, on its removal, was found still to drop, but not to the same extent. He was directed to try to move about on crutches, and to throw some of the weight of his body upon it; but the attempt produced severe pain in the muscles of the inside of the leg, which lasted a few hours, and then subsided. On the following day the muscles in the anterior tibial region were electrified for about a quarter of an hour. The foot however still dropping, the stirrup was reapplied; and five days after he was able to bear upon the foot, wearing the stirrup. without pain. About a month after he left the house, the sole of the foot was then flat on the ground, and the foot itself at right angle with the leg; but the muscles in the anterior tibial region were still wanting in tone. I have seen him several times since; the operation has succeeded so far as recovery of the position of the foot is concerned, but the muscles have not regained their power, and he is obliged to walk with a stick or crutches. The result of this case, as well also as of those *vari* already mentioned as following palsy from teething, led me in two or three instances to try the effect of dividing the Achilles' tendon where horse-foot was just beginning in children so paralysed, but no benefit was gained.

(2) The apparatus I have described for the treatment of club-foot, (*par.* 1379, *note,*) or even the fractured *patella* stirrup, will answer very well for drawing and fixing up the foot in a proper position. Indeed, this distortion of the foot is the most easy of treatment, and might be managed by a careful person merely with a shoe having tapes or straps fixed to its front, and fastened above on either side of a circular bandage above the knee.—J. F. S.]

d.—OF HOOK-FOOT.

(*Talus,* Lat.; *Hakenfuss,* Germ.; *Pied-bot calcarien,* Fr.)

1389. *Hook* or *Heel-foot* consists in the tip of the foot being directed upwards and its back towards the front of the shin-bone, so that the foot forms an acute angle with the leg, often even rests on the shin-bone, and in stepping, the heel only touches the ground. This deformity is always congenital, and manifestly consequent on the position of the *fœtus* in the womb. Often immediately after birth, when the foot is very much drawn up, even if, as I have frequently noticed, it lie upon the shin-bone, it may be brought, by slight force, into its proper place. The contracted muscles are the *m. tibialis anticus*, *extensor proprius pollicis*, and frequently the *m. extensor communis digitorum pedis*, the tendons of which form cord-like projections beneath the skin when the foot is properly placed. The joint connexion between the heel and cuboid bone, and the *astragalus* and navicular bone appear to suffer most; but the cuneiform bones are also drawn back and their joint-surfaces separated from each other in the sole of the foot. The point of the foot is also at the same time often turned outwards if the *m. extensor communis* act violently.

1390. In all the cases which I have hitherto seen soon after birth, it was easy to bring the foot straight, and by means of a curved splint, fastened with a bandage on the front of the leg and back of the foot, to keep it so, and in a short time to effect a cure. If the ailment be permanent and the contracting muscles opposed, this treatment, or the application of a suitable splint, in which case a more considerable atrophy of the leg shows itself than in other curvatures, the division of the stretched tendons, where they project most considerably under the skin, is more certainly efficient.

[Of this disease in an incipient state, I saw the following example under my late colleague Tyrrell, originating in accident and accompanied with severe and constant pain.

Case.—E. G., a tall bony spare widow of forty-six years was admitted

Oct. 24, 1835. A twelve month since she had thrown down a table, the edge of which struck her right foot across the heads of the metatarsal bones, and caused violent pain and swelling. Leeches and poultices were used without relief of the pain, and six weeks after the accident all the toes began to stand upright, which disposition increased; and when she left her bed a fortnight after, she was unable to put the whole sole to the ground, and could walk only on the heel, as she suffered acute pain along the middle of the sole, with pain in the instep, as if a cord were stretched over it, and shooting pain up the front of the leg as high as the knee. For the last six months the pain has been so severe that she has not been able to put her foot to the ground, but has walked on crutches; and once came into the hospital with the purpose of undergoing amputation, which however the Surgeon who attended her did not think justifiable. At present the foot is fixed at right angle with the leg, and all the toes raised at nearly right angles with the instep; all the tendons of the muscles in the tibial region have started and are very tight. She has great tenderness on the inside of her sole and heel, and across the under surface of the heads of the metatarsal bones, but no pain on the outer edge of the sole. There is great pain in the great toe, but not in the others. Pressure along the course of the anterior and posterior tibial and outer cutaneous nerves, to within a hand's breadth of the tubercle of the shin-bone, causes great pain which shoots up into the knee.

As it was thought that these symptoms were produced by the injury which the branches of the anterior tibial nerve had received at the time of the accident, and that she was probably in a condition similar to that of a horse with lame foot, for which Sewell of the Royal London Veterinary College had some years since cut out successfully a portion of the nerve going to the foot, by which its sensibility had been destroyed, and the foot again rendered fit for work, it was determined to perform a similar operation, and accordingly, on

Nov. 6, a cut was made about a hand's breadth above the ankle joint between the *m. tibialis anticus* and *m. extensor proprius pollicis*, and the nerve being found and carefully separated, an inch of it was removed. She suffered extremely whilst the nerve was being disturbed, but after its division the pain ceased, and the instep felt numb. The edges of the wound were brought together with plaster. She passed a good night, and on the following day was entirely free from pain, except slight pain in the great toe. On the third day, the toes had partially dropped towards their natural position, and on the following day were still straighter, and the great toe was numb. As there was a slight erysipelatous blush about the wound, the dressings were removed and a poultice applied. On the fifth day, a smart arterial bleeding, said to be to the amount of twelve ounces, followed the removal of the poultice, but stopped by pressure for ten minutes, and afterwards a compress of lint was bound on the wound. A slight oozing, however, continued, and on the following evening, bleeding recurred, and a similar quantity of blood was lost; it was temporarily restrained by pressure and the wound having been cleared of blood, an aneurysm-needle was passed beneath the anterior tibial artery, which was then tied with a single ligature.

Unfortunately after this time my notes fail, and I cannot get any satisfactory information, except that the woman did not undergo any second operation, and that she left the house four months after still upon crutches, but under what circumstances I cannot ascertain.—J. F. S.]

II.—OF CURVATURES OF THE UPPER LIMBS.

[These curvatures, excepting the fingers, are much less frequent than those of the lower limbs.

A.—OF CURVATURES OF THE SHOULDER.

These are of very rare occurrence, the weight of the arm constantly preserving its position close to the side, and antagonising any of the larger muscles by the contraction of which, alteration of its ordinary situation could be effected. In the contraction of the shoulder the arm is therefore pinned to the side, and the treatment consists merely in the application of blisters, or other irritating remedies for the purpose of inducing absorption of the interstitial deposit originating in rheumatic, or other inflammation of the soft parts about the joint; and the cautious use of extending apparatus, or passive motion, as the case may be.

The division of the tendons, as performed by Dieffenbach for the replacement of a long unreduced dislocation at the shoulder-joint, might certainly be applied to cases of contracted shoulder, but I should think little advantage could be hoped from it.

B.—OF CURVATURES OF THE ELBOW.

Curvatures at this joint, although very commonly resulting from *anchylosis*, or inflammatory deposit in the soft parts about the joints, are, in rare instances, consequent on contraction of the *m. biceps flexor cubiti*, and *m. brachialis anticus*. If arising from the former muscle, any attempt at extending the arm throws its tendon up, as it passes over the front of the elbow-joint, in form of a cord; by which the nature of the ailment is distinctly indicated.

If rubbing and passive motion, and the extending apparatus be unavailing, it will be necessary to divide the tendon of the *m. biceps* beneath the skin in the same way as the Achilles' tendon is divided, and afterwards to apply either a simple splint on the front of the whole lengthe of te arm, and with a bandage to straighten it gradually, as the patient can bear it, or to make use of the extending apparatus.—J. F. S.]

C.—OF CURVATURES OF THE HAND.

1391. Curvatures of the hand are more rare than those of the foot, and mostly depend on unnatural activity of the muscles. There is either permanent bending of the wrist-joint, with simultaneous pronation or supination, or permanent straightening, or the fingers are permanently bent.

a.—OF PERMANENT BENDING OF THE HAND.

1392. In *permanent Bending*, the hand forms with the fore-arm a more or less right angle, and is at the same time in a state of increased pronation and adduction, or increased supination. In both cases the fingers are strongly bent. The bones and ligaments of the *carpus* are separated from each other and outspread behind, but in front (volar surface) are contracted, and form a depression. The hand and fore-arm are more or less atrophic.

Lode (a) distinguishes these two kinds of curvature of the hand, *Talipomanus flexor pronata seu Talipomanus vara* and *Talipomanus flexor supinata seu Talipomanus valga.* All the muscles which bend the whole hand and fingers, and increase the concavity of the hand, in the one case, the pronators, and in the other, the supinators, are contracted at once.

1393. This curvature of the hand may be congenital or acquired. As to its causes, all that has been said upon club-foot applies. I have noticed curvature of the hand as a congenital deformity, once accompanying club-foot and once with horse-foot on the same side. The treatment must be conducted entirely according to the rules laid down for club-foot.

A proper apparatus for straightening the hand is found in Lode, fig. 3.

b.—OF PERMANENT STRAIGHTENING OF THE HAND.

1394. *Permanent Stretching of the Hand*, in which its back is retracted, in a greater or less degree, towards the fore-arm, and is at the same time in a state of increased abduction or adduction, occurs rarely; and in reference to its ætiology and treatment, all that has been previously said applies.

Lode calls this curvature *Talipomanus extensa.* All the extending muscles of the hand and fingers, as well also sometimes those muscles which flatten the hand, sometimes the adductors and abductors, are contracted.

c.—OF PERMANENT BENDING OF THE FINGER.

Dupuytren, Retraction permanente des Doigts; Leçons Orales de Clinique Chirurgicale, vol. i. pt. i. p. 117.

1395. A *permanent Bending of one or more Fingers* may depend on various causes, namely, on diseased changes of the phalanges, on division of the tendons or palsy of the extensors, on a contracting scar in the palm, on destruction of the tendons and sheaths, or contraction of the bending muscles of the hand, and contraction and unyieldingness of the palmar *fascia.* The *diagnosis* of these various causes is really unattended with any difficulty, and depends on the kind of origin, or the perhaps existing scar, or the possibility of moving some of the finger-joints, or on violently straightening the finger and so on. In this respect the curvature of the finger is most important, as consequent on contraction of the palmar *fascia*, because, with definite *diagnosis*, the cure may be more surely effected.

1396. The curvature consequent on contraction of the palmar *fascia* shows itself especially at the ring-finger, mostly in persons who are subject to hard labour, as resulting from inflammatory affection. After violent exertion of the hand, pain frequently comes on, which, however, soon subsides. The fingers are gradually straightened with difficulty, and the ring-finger begins to curve into the palm, at the onset only the first joint bends, but the others follow its movements. In proportion as the ailment proceeds the ring-finger bends still more. At this period no knotty swelling is yet felt on the palmar surface of the ring-finger; its last two joints are straight and movable. The first joint is bent at a more or less right angle, it is movable in its connexion with the *metacarpus*, but the greatest violence cannot straighten it. If the ring-finger be considerably bent, the skin in the palm presents a fold in the direction of the concavity, towards the ring-finger, and the convexity towards the wrist. If the palmar surface of this finger be felt, a stretched cord is found, the point of which is directed towards the first joint, and which may be followed to the upper part of the palm. If the finger be bent, this disappears; but, if its straightening be attempted, the tendon of the *m. palmaris longus* is brought into motion, which extends to the upper part of the palmar *fascia*, and the cord is more tightly stretched.

(a) Above cited.

According to GOYRAUD (*a*) the retraction of the tendinous cords depends on new formations, which pass from the *fascia* to the sheathof the tendon, from it to the lateral parts of the phalanges, and even from one phalanx to another. These bridges are, however, merely growths of the bridges existing in the natural state. SANSON (*b*) also believes that this is the usual cause, and the contraction of the palmar *fascia* only the exception.

If the bending of the finger depend on contraction of the bending muscles, a thick cord is felt, in attempting to straighten it, under the *fascia;* the *m. palmaris* remains immovable, but the bending muscles on the fore-arm are stretched. In a scar, with the muscles attached to it, stretching movements cause pain in the same part; if the hand be bent towards the fore-arm, then the patient can straighten his finger. In palsy, or in division of the tendons of the straightening muscles, the finger is kept permanently shut into the hand, but it may be straightened with a little force, no tight cord is felt, and all the joints are free. In diseased changes in the joints, the finger is more or less bent; the anchylosed phalanges are immovable; but the others can be moved, and no tight cord is felt in the palm. Many occupations give rise to deformity of the joints of the phalanges without *anchylosis*, but with permanent bending; thus is the little finger in knitters and seamstresses; so the ring-finger, and often several fingers of the right hand, in tailors; and in lace-makers the four last fingers of both hands are curved and so on, as consequence of habit; no cord-like stretching is, however, noticed in the hand, and the finger may still be somewhat straightened. Scars may be easily distinguished by their tension in attempting to straighten the finger.

1397. That the cause of this crooking of the finger is an excessive tension of the palmar *fascia*, which has arisen from pressure, and bruising in hard handiwork, DUPUYTREN has proved by careful observation, and by the successful division of this *aponeurosis*. Rubbing, bathing, mechanical apparatus, and the like, have usually no result, or only transient benefit. The latter I noticed in a considerable curvature of the ring-finger from this cause, in which, by continued use of gray mercurial ointment, and animal baths, the proper position and mobility were restored; but shortly after these remedies were given up, the finger again became as strongly crooked as formerly. The division of the palmar *aponeurosis* is most effectual. A transverse cut is made through the skin opposite to the junction of the first phalanx with the metacarpal bone, and then the stretched *aponeurosis* divided in the same direction. If the finger cannot then be straightened, a transverse cut must be made at the joint of the first and second phalanx, or in the middle of the first phalanx. If all the fingers be curved, a transverse cut must be made an inch and a quarter below the former one in the palm of the hand, and the *aponeurosis* divided.

(*a*) SCHMIDT's Jahrbücher, 1835. p. 248.

(*b*) Gazette Médicale, 1835. 1. 8 August.

The wound is to be covered with lint, and upon the back of the hand a flat piece of wood attached; on the front part, which has divisions corresponding to the fingers, the latter must be kept in the straight position, by means of nooses, till the scars are completely formed. If the palmar *aponeurosis* be narrow and stretched like a cord, it is best to determine on its subcutaneous division (*a*).

Goyraud does not divide the skin transversely as Dupuytren does, because, in straightening the finger, the cut in the skin gapes too much; but he cuts through it longitudinally, and through the bridge transversely.

1398. If the cause of the finger crooking be a scar, it must be treated according to rules to be hereafter mentioned. In contraction of the bending muscles, relaxing rubbings must be used on the side of flexion, and irritating rubbing, blisters, and so on, upon the side of extension, and also a corresponding mechanical apparatus. Crooked fingers, from destruction of tendons, or organic changes of the joint-surfaces, and the like, are incurable.

Tenotomy has been variously employed in contraction of the bending tendons and muscles, by which the finger has been perfectly straightened, but the movements of bending were for ever lost: the division may be performed on the phalanges or in the palm.

1399. As to the other curvatures, which are seated in the bones themselves, of the extremities, or in their joints, as for example the bending of the fore- against the upper-arm, or of the leg against the thigh, the bowing of the bones of the leg, the inward or outward turning of the knee-joint, and so on, what has been already observed generally, and the circumstances mentioned in the several kinds of curvature, applies to them. Their *treatment* must also be by internal and external remedies, as well as by the construction of suitable apparatus, which must always act by spring-power, and, if these be useless, and the cause be in the shortening of the muscles, if their tendons be accessible, the division of the stretched tendons and *aponeuroses* are easily effected. In such cases, the *m. pectineus* and *sartorius*, the tendons of the *m. biceps femoris*, *semitendinosus*, *semimembranosus* and *gracilis*, the *fascia lata* in the region of the intermuscular *aponeurosis* and the *m. biceps brachii* have been cut through.

1400. Every swelling produced by partial expansion of the cavity of an artery, or, after previous division of its coats, by effusion of blood into the surrounding cellular tissue, is called an *Aneurysm* (*Aneurysma*, Lat.; *Pulsadergeschwulst*, Germ.; *Anévrisme*, Fr.) In the former case it is named a true, (*Aneurysma verum*,) and in the latter a *false* or *spurious Aneurysm* (*Aneurysma spurium*.) Some writers have also mentioned a *mixed Aneurysm*, (*Aneurysma mixtum*,) where either after the external arterial coat is divided, the internal expands, or the contrary (*a*). This designation, however, is also used for the case when a true aneurysm bursts, and the blood is effused into the cellular tissue (*b*). The mixed aneurysm, taken in the former sense, does not exist. Breschet (*c*) has, however, by close examination, determined that the middle coat of the artery is torn, and a sac-like expansion produced by the protrusion of the inner coat through the opening in the middle, and by the expansion of the external coat. A combined division and enlargement of an artery and vein is called a *Varicose Aneurysm*, or *Aneurismal Varix* (*Aneurisma varicosum seu venosum*, or *Varix aneurysmaticus*.) If the expansion affect several branches coming from different trunks, and anastomosing branches and their arches, with or without partial lateral enlargement of their walls, such are distinguished as *Branching Aneurysm*, or *Aneurysm by anastomosis* (*Aneurysma anastomosium seu anastomoticum*, von Walther; *A. spongiosum seu cirsoideum*, Breschet; *Varix arteriosus*, *A. per anastomosin*.)

(*c*) Mémoire Chirurgicale sur différentes espèces d'Anévrysmes. Paris, 1824. 4to., with six plates.

[The writings of the ancient physicians show their acquaintance with aneurysm, which they described as of two kinds; one, the consequence of a wound in bleeding from the vein in the arm or spurious aneurysm, which would seem to have been of not unfrequent occurrence, as they are best informed about it; and the other by dilatation of the artery without injury, or true aneurysm. I have selected passages from **Galen**, **Ætius**, and **Paul** of Ægina, which are the foundation of the opinions long and subsequently held by writers on this subject.

Galen (*a*) says:—"When an artery is expanded, the disease is called an aneurysm. This happens when, the vessel being wounded, the adjoining skin cicatrizes, but the wound still remains in the artery, which neither unites nor heals, nor is filled up with flesh. Such diseases are known by the pulsation of the arteries, but when pressed, all the swelling disappears, the substance producing it returning into the artery, and which I have elsewhere shown consists of thin and yellow blood mixed with thin and much spirit. Forthwith is this blood hotter than that in the veins, and when the aneurysm is wounded, it darts forth and can with difficulty be stopped. But in *œdema* the substance yields to the pressure of the finger, and the ,limb pits, but there is no pulsation in this disease, and the colour is whiter, and the *œdema* is much more spread and greater than in aneurysm, except when a *thrombus* having arisen from it, produces gangrene." In another place (*b*) **Galen** says:—"Aneurysm is the dilatation of a vein, or the dispersion of the spirituous matter by its bursting beneath the flesh."

Ætius (*c*) describes the signs of aneurysm as "a tumour of small or large size, of one colour, free from pain, soft to the touch, and having a spongy looseness. It yields so to pressure of the fingers as to seem almost to disappear, but on the removal of the fingers it very quickly returns, which is especially observed in aneurysm and the rest that occur without a wound. But when there has been a previous wound of the artery, and the skin uniting, there is also accompanying dilatation of the vessels, the tumour is not equally soft, for the blood being more copious than the spirits, collects in clots and swells out the tumour."

Paul, of Ægina (*d*), proceeds farther, and distinguishes spontaneous aneurysm from that produced by accident. After having quoted **Galen's** definition and symptoms, he says:—"But I distinguish the one from the other thus: those which arise from a dilated artery are more bulky and deeply situated, and on examination with the fingers a sort of noise is heard; but no noise is heard in those caused by rupture, which are more round and arise superficially. He advises different treatment for the two forms of disease, as will be presently mentioned.

John Hunter defines aneurysm as "the dilatation of the coats of an artery, arising probably either from disease or accident, producing weakness, which becomes the remote cause, while the force of the circulation is the immediate cause. It probably may also arise, however, from a disproportion in the blood's motion, and then the disproportion between the force of the circulation and strength of the artery is both the remote and the immediate cause; but this is probably only in the larger arteries, where the force is greatest." (pp. 543, 44.)]

1401. In true aneurysm the walls of the artery are either expanded only at a small part of their course, (*Aneurysma verum circumscriptum*,) or the expansion affects a larger extent, and is gradually lost (*Aneurysma verum diffusum.*) False aneurysm is also divided into the *circumscribed* or *consequent*, (*Aneurysma spurium circumscriptum seu consecutivum*,) and the *diffused* or *original* (*Aneurysma spurium diffusum seu primitivum.*) In the former case the blood is effused under the cellular tissue of the artery, and outstretches it into a sac; in the latter, all the coats of the artery are divided, and the blood is poured forth into the interspaces of the whole limb (*par.* 278.)

Breschet distinguishes four principal kinds of true aneurysm according to the different form of the expansion of the arterial canal. 1. The *true sac-shaped aneurysm*, in which the artery exhibits at one part of its tube a fulness like a little sac,

(*d*) Βιβλια επτα, book vi. chap. xxxvii. p. 188. Basileæ, MDXXXVIII. fol.

originating in the expansion of all the coats of the arteries. 2. The *spindle-shaped aneurysm*, in which all the coats of the whole tube of the artery are expanded, but narrow above and below, like a spindle. 3. The *true cylindrical aneurysm*, in which the canal of an artery is, for a greater or less distance, more or less regularly expanded. 4. The *true varicose aneurysm*, or *aneurysmal varix*, in which there is an expansion of the artery, to a greater or less extent of its length, often throughout the entire length of the trunk of the vessel, and of its principal branches, exactly as in varicosity of the veins. Besides this transverse expansion, there is also a lengthening of the vessel, which becomes bent, and describes more or less numerous and considerable curves. There are also sometimes observed, besides this, sudden expansion of the whole arterial cylinder, at certain parts, knots; or little circumscribed aneurysms, which are true sac-shaped and often mixed aneurysms. Very frequently the walls are thinned, softened, and falling together like those of varicose veins, whilst in true cylindrical aneurysm the walls are thickened. The artery affected with *varix* has great resemblance to a varicose vein; the pulsation, however, always presents a distinguishing and determinate character.

1402. The symptoms which characterize aneurysm are the following:—A little elastic pulsating swelling, which diminishes on pressure, and soon returns on its withdrawal, arises at some one spot corresponding to the course of the artery. The pulsation ceases when the artery is compressed between the swelling and the heart, and the former becomes generally less tense. If the artery be compressed below the swelling, the pulsation becomes more bounding and distinct. The tumour is usually free from pain, the skin over it unchanged, and it quickly enlarges to a considerable size. In proportion as the swelling increases, the blood contained in it becomes more solid by coagulating, and can be no longer got rid of by pressure; the pulsation is weaker, and often entirely lost (1). When the tumour has acquired considerable size, it acts injuriously by its pressure and expansion upon the neighbouring parts; the circulation in the diseased artery, in the other blood and lymphatic vessels, is interfered with; the nerves are compressed; the nourishment, warmth, and sensation of the part are diminished; the limb becomes œdematously swelled; the tumour is covered with varicose vessels, and becomes bluish; and the surrounding muscles, and bones even, may be destroyed by the constant pressure and absorption. In consequence of the expansion of the parts covering the swelling, they at last inflame; at the most prominent part an abscess, or commonly a slough is formed, after the separation of which the coagulated blood is discharged, and a dangerous or fatal bleedinge nsues (2). The coverings of the tumour may be also torn by gradual distension. Its size may even become so great, that by the pressure and destruction of the surrounding parts, the nourishment of the limb may be entirely prevented, and its death caused (3).

If the aneurysmal sac increase, it attaches itself to the surrounding parts, which are thickened by inflammation and by the exudation of plastic lymph, and thus enabled, although the coats of the artery be torn, to prevent the penetration of the blood into all the interspaces of the part. If, however, the aneurysmal sac tear suddenly before these adhesions are formed, the blood is poured forth into all the interspaces of the part.

[(1) "The coagulation takes place," observes JOHN HUNTER, "at the most distant parts from the direct current of the blood: the firmness and colour of the *laminæ*, in different parts of the tumour, are such that it is easy to distinguish an old *coagulum* from a new one; the external *laminæ* are of a dusty brown colour, and these *laminæ* grow gradually redder as we advance inwards towards the current of the blood. As the dilatation increases, the coats of the artery are thickened by the thickening process, or the cellular membrane already thickened becomes firm, and adheres from a consciousness of weakness. When the aneurism proceeds to this state it generally gives way to the circulation. It must be observed that the force of the blood on the sides of the sac diminishes in an inverse ratio to the increase of its sides, which, therefore, are longer in dilating than might be imagined; but after proceeding to a certain length, the adventitious coat gives way, and the blood is effused into the surrounding cellular membrane, producing distension; and when the artery is a considerable one, there is an obstruction to the blood's motion in the collateral branches, producing mortification. When the artery opens externally, it is always on that side where the artery gives way most." (p. 546.)

(2) The mode in which an aneurysm bursts externally is thus described by **John Hunter**. "When an aneurism is in an artery whose dilatation brings it to the skin, the *coagulum* comes first, and obstructs the circulation in the skin; the skin inflames and mortifies, forming a black slough, which dries and adheres to the *coagulum*. As the slough separates there is an oozing of blood at the edges, which becomes more and more, till at last in a large artery, as the *aorta*, the plug may be wholly pushed off and the patient die instantly. If in a smaller artery, death will be more gradual." (p. 546.)

Hodgson makes the following good remarks upon the bursting of "aneurisms, which, like abscesses, generally proceed towards the surface of the body; but in this respect they are very much influenced by the situation and the side of the vessel from which the disease originates. When the sac points externally it rarely or never bursts by laceration, but the extreme distension causes the integuments and investing parts to slough, and upon the separation of the eschar the blood issues from the tumour. A similar process takes place when the disease extends into a cavity which is lined by a mucous membrane, as the œsophagus, intestines, bladder, &c. In such cases the cavity of the aneurism is generally exposed by the separation of a slough which has formed upon its most distended part and not by laceration. But when the sac projects into a cavity lined by a serous membrane, as the *pleura*, the *peritoneum*, the *pericardium*, &c., sloughing of these membranes does not take place, but the parietes of the tumour, having become extremely thin in consequence of distension, at length burst by a crack or fissure, through which the blood is discharged. I have," says he, "examined aneurisms that have burst into the cavities of the *pericardium*, the *pleura*, and the *peritoneum*, and the opening has always been formed by laceration, and not by sloughing: on the other hand, all the instances of this disease that I have seen, in which aneurisms burst upon the surface of the body or into cavities lined by a mucous membrane, the opening has been the consequence of sloughing and ulceration, and not of laceration." (pp. 85, 6).]

(3) When aneurysms burst into mucous canals, they do not generally seem to protrude much into their cavity, but the walls of the aneurysm and of the canal becoming adherent, ulceration takes place, and in this way the blood escapes from the sac and often very quickly destroys the patient.

The same thing also happens in that very rare termination of aneurysm by bursting into another artery, an example of which is given by Dr. **Wells** (*a*), and the preparation is in the Museum at St. Thomas's Hospital. The following is an extract of this interesting case:—

A fair-complexioned, thin, and temperate man, 35 years old, was in 1789 affected with symptoms supposed to denote the approach of pulmonary consumption, but after some time they disappeared. Nine years after he had a slight attack of hemiplegia, from which, however, he soon recovered. In March, 1804, he was frequently troubled with noise in his ears, flatulence, and pains in his hands and feet, from one or other of which he was never after free, but he never complained of any unusual feelings about his chest. On the 11th of August, 1807, having fatigued himself a good deal with walking, and eaten a full dinner, he fell asleep, awoke much refreshed, and played with his children in the garden. "While thus amusing himself, he was suddenly seized between eight and nine in the evening with a sense of great oppression in his chest. He soon after became sick and vomited; in the matter thrown up some streaks of blood were observed. He now went to bed, but though the weather was warm, and he was covered with bed-clothes, his skin felt cold to those who were attending on him. Soon after midnight he laboured under a constant desire to cough, and was continually expectorating mucus tinged with blood. His body was moistened with a cold sweat, his pulse was extremely feeble, sometimes it was scarcely perceptible." He continued getting worse through the night, "his breathing became difficult, and he frequently tossed and writhed his body as if he was suffering great pain and uneasiness, About a quarter past five he suddenly became worse, and expired. Almost immediately before his death he complained much of heat in his chest, and threw off the clothes to cool himself." On *examination*, "the blood-vessels of the lungs were found very much distended, and there was also a considerable quantity of blood in the air-cells. The right lung adhered slightly to the ribs and *pericardium;* but this seemed to have

---

(*a*) Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge, vol. iii.

been the consequence of some disease which had existed long before death. Each cavity of the chest contained about ten ounces of a fluid highly tinged with blood; the *pericardium* contained about two ounces of a fluid similarly tinged. The ascending *aorta* was distended to about the size of a large orange. The tumour adhered to the pulmonary artery, just before its division, into the right and left branches. Within the circumference of this adhesion there was a narrow hole, by means of which a communication was formed between the two arteries. The cavities of the heart, and the great blood-vessels, were very much distended with blood." (p. 88.) In the Museum at the Royal College of Surgeons, there is one specimen of aneurysm of the arch of the *aorta* burst into the pulmonary artery close to its valves by an oval opening half an inch in its greatest diameter; and also a second, in which there is a small round aperture between the sac and the trunk of the pulmonary artery. The patient died of jaundice and dropsy; but the aneurysm was not indicated during life.

It may be here mentioned that the pressure of an aneurysmal sac will sometimes produce obstruction in the neighbouring vessels. In St. Thomas's Museum there is an example of complete obstruction of the *superior vena cava*, and *vena innominata*, by an aneurysm of the aortic arch involving also the *arteria innominata ;* in the Museum at Fort Pitt, Chatham, is one in which the *superior vena cava* is obliterated; and in the College Museum, one in which the *superior vena cava* is almost obliterated.]

1403. The distinguishing characters of circumscribed true and false aneurysm, are usually described as the following :—True aneurysm quickly diminishes on the application of pressure, though it reappears almost as soon as the pressure is removed: false aneurysm only disappears gradually, and returns slowly after pressure has been taken off, because the blood can only gradually pass from the sac into the artery, and from it again into the sac. A distinct sound is often observed when the blood again flows into the sac (1). The pulsation is weaker in false than in true aneurysm, and sooner becomes indistinct in the enlargement of the swelling. The aperture by which the sac of the false aneurysm is connected with the cavity of the artery, is narrow in comparison with its base; in partial extension of all the arterial coats, the entrance for the blood is just as wide as the base of the sac. When the extension occupies the whole tube of the artery, the swelling is always cylindrical or egg-shaped, yields easily to pressure, and in the dead body is always found smaller than it was during life. The form of the false aneurysm is irregular, and continues the same in the corpse. In the sac of a true aneurysm, layers of coagulated blood are never deposited, which is always the case in false aneurysm, with very rare exceptions (*a*). The more all the coats of the artery are expanded the more they are thinned, whilst, on the contrary, the sac of a false aneurysm increases in thickness (*b*). However, in true cylindrical aneurysm the walls may be equally thick, so that, if cut through vertically to its axis, the walls do not drop (*c*).

[(1) LAWRENCE (*a*) observes :—"There are some instances in which pulsation cannot be felt, in which it may be heard, either by the application of the ear directly applied to the tumour, or through the medium of the instrument called the stethoscope. The sound that is communicated in either of these cases is very peculiar, the sound produced by the passage of the stream of blood from the opening in the artery leading to the aneurismal sac. The blood passes through comparatively a contracted orifice, to enter into a large cavity, and each jet of the blood propelled into the aneurismal tumour by the contraction of the heart, produces a sound which is something like that of the sound of blowing through bellows—*whih, whih, whih ;* you will hear a succession of these; and hence the French, in my opinion, have very appositely characterised it by the term *bruit de soufflet ; soufflet* is the term used for bellows: and, in fact, it means 'noise of a bellows;' and, in short, it cannot by any terms be more clearly illustrated." (p. 160.)

(*a*) HODGSON, above cited, p. 82. (*b*) SCARPA.
(*c*) BRESCHET, above cited.

I cannot assent to several of the conditions laid down by **Chelius**, as distinguishing true from false aneurysm. The diminution of the bulk of a true aneurysm depends materially on the stage at which it has arrived; if it be recent, and there be little or no lining of clot, it does diminish readily on pressure of the artery between the sac and the heart; but the diminution under these circumstances is less and less, in proportion to the increased bulk of the sac, so that, in a large aneurysm there is, comparatively, little diminution of size, though the current of blood be stopped. False aneurysm diminishes still less, and often, indeed, when the blood continues, as it commonly does, pouring into the cellular tissue it there coagulates, scarcely any perceptible diminution of size is made by pressure on the artery between it and the heart. And a true aneurysm which has burst a sac beneath the skin, as sometimes happens, is similarly circumstanced. The pulsation is generally less distinct in a false than in a true aneurysm; but this also depends on the period and extent occupied by the blood which has escaped, and is proportionally less, the greater the quantity of blood poured out. The external form of a false aneurysm is undoubtedly irregular, as it much depends upon the looseness of the surrounding cellular tissue, and whether the part be or be not enveloped in a tendinous sheath; but the immediate sac, consisting only of more or less numerous layers of coagulated blood, which, as they continue to form, thrust the loaded cellular tissue away from the artery, and hollow it out for their own lodgment, is generally of a regular oval form, and has at one or other part an aperture, by which blood continues escaping and gorging the cellular tissue surrounding the false sac, till at last it distends the skin so much that it mortifies and gives way at one or more points, and bloody serum and clots mixed with ill-formed pus, which is commonly produced towards the termination of the disease, begin to be discharged, and increase in quantity till the false sac itself break away and the blood readily makes its way out. I cannot understand the observation, that "in the sac of a true aneurysm layers of coagulated blood are never deposited," which is, most undoubtedly, incorrect in all cases where the aneurysm results from ulceration or tearing of one or other coats of the artery; for very speedily after a pouch is formed, layers of clot begin to form. And even when the disease only depends on dilatation of the arterial coats, though at first there be no layers of clot, yet as the disease proceeds, they are certainly formed, although **Hodgson** denies it, and says:—"In those sacs which consist either in a general or partial dilatation of the coats of the vessel, I have never met with it." (p. 82.) As to the difference of thickness of sac in true and false aneurysm, although in the former the coats of the artery thin, as the disease increases, yet there is a continued slow inflammatory action going on upon the external surface of the sac by which its thickness is preserved, till the parts by which it is surrounded having been either absorbed or stretched to bursting by its size, the sac itself is the only remaining resistant to the impulse of the blood, and in its turn yields, thins, and at last it bursts. As to the thickening of a false aneurysmal sac, it continues indeed so long as the surrounding cellular tissue confines and supports it, but when the tissue is absorbed or sloughs, the want of support is here also felt, and the false sac thins, yields, and bursts as in true aneurysm.—J. F. S.]

1404. The distinction of aneurysm from other swellings is grounded on the pulsation, the diminution by pressure, the reappearance when the pressure is removed, and the position corresponding to that of the course of an artery. When therefore the pulsation is indistinct, or not at all perceptible, and the swelling cannot be diminished by pressure, it must be the more carefully examined, and attention paid to its origin and its early condition. Swellings in the neighbourhood of a large artery, or lying upon it, participate in the pulsation, which, however, to a practised touch is easily distinguishable, as it consists only in a raising and sinking of the swelling; but if such swelling contain any fluid which undulates by the imparted motion, the *diagnosis* is doubtful: a degree of certainty, however, may be attained, if the artery be compressed above the swelling, and the latter be then properly examined (*b*).

[Aneurysms are sometimes mistaken for abscesses. **Dupuytren** witnessed a case in which the blood issuing from an aneurysm of the arch of the *aorta*, made its way behind the breast-bone into the bottom of the neck, and there formed a tumour, which,

---

(*a*) Lect. on Surg.; in Lancet, 1829-30, vol. ii.

(*b*) **Ribes**, Mémoires et Observations d'Anatomie, de Physiologie, de Pathologie, et de Chirurgie, Paris, 1841. vol. i. p. 255.

being mistaken for an abscess, was punctured, and gave rise to repeated, and at last fatal bleedings. **Richerand** (*a*) says, that "**Ferrand**, principal Surgeon at the Hôtel-Dieu, thinking to open an abscess in the armpit, plunged his knife into an axillary aneurysm, and killed his patient." (p. 72.) **Astley Cooper** mentions an instance of an aneurysm which had presented in the loin, being punctured, under supposition of it being a lumbar abscess; the mistake, however, being ascertained, the edges of the wound were immediately brought together and healed, and the patient died by the tumour afterwards bursting internally. (p. 35) I myself recollect a spurious aneurysm, after venesection, having been punctured as an abscess; the bleeding was stopped immediately, but about twenty hours after, as the girl was dressing her hair, the bandage slipped off, a violent gush of arterial blood followed, and she lay in great jeopardy for many hours before she was in a fit state to have the artery secured.

On the other hand, a pulsating tumour may be mistaken for an aneurysm, an example of which is mentioned by **Warner** (*b*), in a boy who had his breast-bone much fractured by a fall, and came to Guy's Hospital a fortnight after. "There was an evident separation of the broken parts of the bone, which were removed at some distance from each other. The intermediate space was occupied by a tumour of considerable size; the integuments were of their natural complexion; the swelling had as regular a contraction and dilatation as the heart itself, or the *aorta* could be supposed to have. Upon pressure, the tumour receded; upon a removal of the pressure, the tumour immediately resumed its former size. * * * The event was, the tumour burst in about three weeks from his admission, discharged a considerable quantity of matter, and the patient did well by very superficial applications." (p. 155.)

Sometimes a large *varix* of the accompanying vein may turn so completely over the artery as to hide it completely, and receive its pulsation. In St. Thomas's Museum there is a very fine example of this disease in the internal jugular vein, the swelling of which, from its size, must have occupied nearly the whole of the one side of the neck. Such cases may be distinguished by pressure of the swelling at its farthest extremity from the heart, in which case its size will diminish, whilst if pressure be made between it and the heart its bulk must be increased, which is the very reverse to aneurysm.

Tumours of any kind upon an artery will often acquire pulsation from it, and be liable to mistake; their unvarying size, however, and commonly the cessation of the pulsation when the swelling is lifted up, will generally determine their true character.—J. F. S.]

1405. Aneurysms arise either of their own accord, or after determinate external influence (*A. spontaneum* and *traumaticum.*) In the former case they occur generally at more than one spot, either at once or consecutively, and thus show that a peculiar morbid condition spreads more or less over the arterial system. This is observed most commonly in persons who are subject to rheumatism, gout, *scrofula*, *syphilis*, who have used much mercury, and have drank spirits to excess. In these cases there frequently arise inflammation of the internal coat of the artery, ulceration, loosening, thickening, even ossification between the internal and middle coats, by which the walls of the artery yield to the pressure of the blood, or the internal and middle coats are torn or destroyed. The external influences which produce aneurysm are wounds, violent efforts in lifting heavy weights, in jumping, in vomiting, coughing, and the like. These circumstances (wounds naturally excepted) produce aneurysm the more readily, if the coats of the artery have been changed by disease, as above mentioned.

[**Richerand** mentions a curious circumstance in reference to "a class of persons who almost always die of aneurysm, and whom he noticed whilst engaged with anatomy. These were the servants of the amphitheatre, whose business it was to bring the subjects and remove the refuse of the dissections. I never saw one," says he, "who did not abuse spirituous liquors, and was not constantly drunk; and to this were added the feebleness resulting from such excess, the fatigues of so disgusting and laborious an occupation which occupied their nights, the exertions required to carry bodies often too heavy for a single person, wearied with sleep and drunkenness." (p. 71.)

(*a*) Nosographie Chirurgicale, vol iv. Fourth Edit. Paris, 1815.
(*b*) Cases in Surgery. London, 1784.

Guthrie also observes:— "The exertion in general is infinitely greater in the man than in the woman; and I think this, combined with the freer use of ardent spirits, a much more likely predisposing cause than either *syphilis* or mercury." (p. 87.)

With regard to the age at which aneurysm occurs, **Astley Cooper** observes (*b*):— "The period of life at which they most frequently occur is between thirty and fifty years; at that age in the labouring classes the exertions of the body are considerable and its strength often becomes diminished: in very old age this complaint is less frequent, as muscular exertion is less. The greatest age at which I have seen aneurism has been eighty years; this was in a man for whom I tied the popliteal artery in Guy's Hospital, for popliteal aneurism; and, notwithstanding his advanced age, I never had an operation succeed better. I also operated on a man of sixty-nine years, and that case also did well. A boy, in St. Thomas's Hospital, had an aneurism of the anterior tibial artery, who, I was informed, was only eleven years old. The man of eighty was the oldest, and the boy of eleven the youngest, which I have seen with aneurism." (pp. 40, 1.)

As regards the frequency of aneurysm in the sexes, **Wilson** (*a*) remarks, that shortly before **John Hunter's** death, he heard him state that he had only met with one woman with true or spontaneous aneurysm. **Astley Cooper** says:—"In forty years' experience, taking the hospital and private practice, I have seen only eight cases of popliteal aneurism in the female, but an immense number in the male. The aneurisms which I have seen in the female, have been the greater number in the ascending *aorta* or the carotid arteries." (p. 41.) Of the sixty-three cases referred to by **Hodgson**, seven only were females, and the other fifty-six males. (p. 87.) **Guthrie** states, that he "does not recollect having seen more than three women suffering from popliteal aneurism; and it is probable that they are found, on an average, at least, from twenty to thirty times, in men for once in woman. The structure of the vessels is the same, but the mode of life is different." (p. 87.) **Lisfranc** (*b*) mentions that of one hundred and fifty-four cases which he had collated, one hundred and forty-one were males, and thirteen females. I myself, in the course of thirty years, do not recollect more than three external aneurysms, which were popliteal, in females.—J. F. S.]

1406. Aneurysm may occur in all arteries: the internal arteries are, however, more frequently attacked with it than the external, the reason of which may be, that the nearer the arteries are to the heart, the thinner are their walls in proportion to their diameter, consequently they are less capable of withstanding a violent pressure of the blood. The curves, also, which the arteries describe in their course, have an influence on the more frequent origin of aneurysm. Aneurysm of the arch of the aorta is most frequent; next comes aneurysm of the popliteal, then of the inguinal, axillary, and carotid arteries. False aneurysm, as a consequence of the wound of an artery, occurs most commonly in the brachial, after an unlucky blood-letting.

["The force of the heart, however," says **John Hunter**, "has some power in operating as a remote or first cause of aneurisms. Aneurisms are most frequent in the larger arteries, as at the arch of the *aorta*, and more frequent in the second order of arteries than in the third; but they are sometimes found even in the fourth and fifth. * * * The nature of the artery contributes likewise, the structure of the large arteries being chiefly of elastic matter, and not near so muscular as the small ones, which have therefore greater powers of resistance." (pp. 544, 45.)]

Of the comparative frequency of aneurysm in the different external arteries, the following tables are given by **Hodgson** and by **Lisfranc**:—

Hodgson.

Popliteal and Femoral	14 males.
Ditto	1 female.
Carotid	2 males.
Subclavian and axillary	5 "
Inguinal	12 "
Total	34

Lisfranc.

Popliteal	59
Femoral, at the groin	26
" other parts	18
Carotid	17

(*a*) Lectures on the Blood, and the Anatomy, Physiology, and Pathology of the Vascular System. London, 1819. 8vo.

(*b*) Des diverses Méthodes et des différens Procédés pour l'Oblitération des Artères dans le traitement des Anévrysmes. Paris, 1824. 8vo.

Not unfrequently there is more than one aneurysm existing at the same time: it, therefore, becomes a matter of high importance to make a careful examination of the whole of a patient's body upon whom it is proposed to operate; for if there be any internal aneurysm, it is useless to subject him to an operation from which he can derive no real benefit, as the internal aneurysm will sooner or later destroy him. **Astley Cooper** mentions that "the elder **Cline** was about to operate upon a man in St. Thomas's Hospital who had a popliteal aneurism, but deferred it on account of the patient's complaining of a pain in his *abdomen.* A few days afterwards the man died suddenly, and, on examination, an aneurism was found between the two emulgent arteries, which had burst into the abdomen." (p. 30.) Or the excitement of an operation may cause the bursting of an internal aneurysm, which happened with a patient upon whom **Astley Cooper** had commenced operating for popliteal aneurysm. "The patient stretched himself on his back, and his urine flowed from him; * * * he gave a deep gasp, and in a few minutes was dead. The next day," says **Cooper**, "I opened the body, and found the *pericardium* distended with blood, which had escaped from an opening seated at the beginning of the *aorta,* immediately above the semilunar valves." (p. 29.) The preparation is in the Museum at St. Thomas's Hospital.

Sometimes many aneurysms are met with in the same person. **Astley Cooper** tied the external iliac artery for an aneurysm at the origin of the *profunda,* and another in the middle of the thigh; the man died afterwards of aneurysm at the bifurcation of the *aorta,* which burst into the belly. "Upon examination, an aneurism was found in each ham; one at the bifurcation of the *aorta,* one at the origin of the *arteria profunda,* one in the middle of the thigh, and two between the popliteal aneurism and the femoral, making in all seven aneurisms." **Tyrrell**, in a note upon this case, mentions another instance in which he operated on a man who was afterwards found to have seven aneurisms." The operation was performed for a popliteal aneurysm in the left ham. "Whilst feeling in the course of the artery, before commencing the operation, I found," says **Tyrrell**, "a small aneurism near the part in which I had intended to secure the vessel; this led to a more minute examination of the patient, and at that period another aneurism was found just above the tendon of the *triceps,* on the same side, making two femoral aneurisms and a popliteal on the left side. On the right side the artery felt dilated in several places, but a little below **Poupart**'s ligament an aneurism existed as large as an egg. After further consultation, it was decided that I should tie the femoral artery between the two small aneurisms, as we feared that a ligature in the external iliac would not command the hæmorrhage from the aneurismal sac," (which had been punctured to ascertain its character, previously very doubtful.) The space between the two aneurisms in the femoral was about an inch, or an inch and a half, appeared sound, and a ligature was applied on it. During the following three weeks the limb became gangrenous, and the aneurismal sac in the ham sloughed, exposing the thigh-bone, but amputation was not performed, for fear of the diseased condition of the artery. "The ligature did not separate from the wound until the sixth week, and the patient lingered till the 28th of July," (eight weeks and a half after the operation.) "The popliteal and inferior femoral aneurisms of the left side had been destroyed by the sloughing; that above the ligature was not closed. On the right side were found three femoral aneurisms, and a small popliteal, making in all seven; besides some dilatation of the *aorta,* immediately above the bifurcation," (pp. 38,'9.)

Still more remarkable is the case mentioned by **Pelletan** (*a*), who observes:—"I have often seen numerous aneurysms affecting indifferently the large and small arteries, but specially those of size; I counted 63 in one man, from the size of a filbert to that of half a pullet's egg," (p. 1.) And in another case, related by **Cloquet** (*b*), "all the arteries were studded with aneurismal tumours from the size of a hempseed to that of a large pea. Some were on the *aorta* and its principal divisions, but they projected little and were much less numerous than on the arteries of the limbs," which, "on many parts of their length, formed kinds of necklaces; all the swellings were numerous and close together. Those of the lower limbs were perhaps less numerous; without exaggeration they might be estimated at several hundreds. The arterial walls seemed unaltered in structure, except at the swellings, where the tunics were dilated and thinned. In none did I observe rupture of the inner or middle coats." (p. 86.)]

1407. The old opinion that spontaneous aneurysm almost always depends on an expansion of all the arterial coats, has been disputed by many writers, but most efficiently by **Scarpa**, and *the origin of aneurysm placed in a tearing of the internal coat of the artery, effusion of blood through this tear, and expansion of the cellular sheath of the artery.*

(*a*) Clinique Chirurgicale, vol. ii.

(*b*) Pathologie Chirurgicale. Paris, 1831. 4to.

The correctness of this opinion is grounded on the condition of the arterial coats in their natural state, and on the careful examination of aneurysmal arteries. For the internal and middle coats of arteries cannot, on account of their slight degree of elasticity, permit any great degree of extension without tearing; whilst, on the contrary, their external or cellular coat is in the highest degree extensible. Examination shows that in all large aneurysms their proper sac communicates with the cavity of the artery by a large or small opening, frequently, as it were, fringed, and often hard and callous; that, therefore, the swelling never includes the whole tube of the artery, as would be the case in expansion of all the arterial coats, but is connected with the artery like an appendage fixed on a stem. Further, that in the wall of the artery, opposite the torn part, the several coats are found in their natural condition, and can be decidedly distinguished from each other; that in spontaneous aneurysm the internal coats are usually changed in a manner (*par.* 1405) which, indeed, favours their tearing, but not their extension. Also, in expansion of all the coats of the artery, no collection of coagulated blood can take place, as the blood always remains within the cavity of the vessel. The reason, however, why it is so easily assumed that the sac of the aneurysm is formed of all the coats of the artery, is founded on the cellular tissue being always considerably thickened, and at the commencement of the tear being adherent, in the closest manner, to the internal coats of the artery, which are here always more or less disorganized, often quite brittle. Besides, also, every remark usually applied to aneurysm by expansion, is equally applicable to aneurysm by tearing. Only in the *aorta*, near to the heart, does SCARPA admit the possibility of simultaneous expansion of all the arterial coats; however, even here it can only attain a certain degree, without tearing of the internal coat.

[JOHN HUNTER somewhat inclines to a diseased condition of the artery; for he says:—"It would appear that there must be a specific disease of the artery in most cases, for dilatation is too local for so general a cause as the force of the heart." (p. 545.)]

1408. Close and careful, however, as are the observations of SCARPA, and valid as is his opinion against the often too ready assumption of an extension of all the arterial coats in aneurysm, their truth cannot, however, be admitted in every case. Examinations instituted by the closest observers, show that the arteries are subject to an expansion, not only of their whole tube, but also of particular parts (*a*). SCARPA himself admits the possibility of extension of all the coats in the arch of the *aorta*. In old persons, especially females, the expansion of the arch of the *aorta* without degeneration or tearing, is twice as frequent. Even the trunk of that vessel has been found throughout regularly expanded to nearly double its size (*b*). Enormous expansion of the *aorta* and pulmonary arteries, are a common appearance in diving animals.

On examining an aneurysm in which the internal coat has been torn, and a considerable sac formed in the cellular coat, the area of the artery is often found considerably enlarged, at the place where the tear has occurred, and no other change in the inner and middle coats of the artery, than that they are expanded and thinned. The enlargement of the neighbouring branches of the arteries, if the circulation be in any way checked in the principal trunk, and the frequently considerable expansion of the capillary vessels in the branching aneurysm, presently

---

(*b*) MECKEL, Handbuch de pathologischen Anatomie, vol. ii. pt. i. p. 244.

to be considered, contradict SCARPA's opinion. From these reasons, however, it only follows, that a simultaneous expansion of all the arterial coats is possible, but that when it attains a certain degree, tearing of the internal and middle coats occurs; consequently, a *false aneurysm* is produced from a *true aneurysm*.

1409. Although the above-mentioned (*par* 1372) results are the common terminations of aneurysm, and the disease, if left to itself, nearly always ends fatally, yet, however, it is capable of a spontaneous cure, which may be brought about in different ways.

1. If the aneurysmal sac attain considerable size, it may compress and obliterate the artery. This is the more rare case (1).

2. A severe inflammation which attacks the whole aneurysmal sac, and runs into suppuration or gangrene, may act so violently upon the artery itself, that its adhesion may be produced, and no bleeding occur after the bursting of the sac; but the suppurating part closes without any trace of aneurysm.

3. A deposit of clot in layers may take place in the sac, by which its cavity may be diminished, and at last even filled up. The clot extends into the canal of the artery, and closes it to the next collateral branch, above or below the swelling (2). This kind of spontaneous cure of aneurysm is announced by the swelling becoming solid, and by a weaker or completely stopped pulsation (*a*).

4. The clot contained in the sac may be converted into a solid, fleshy, steatomatous mass, by which the bursting of the sac is prevented; in which case, however, the area of the artery is preserved, and the sac gradually diminished by absorption (*b*).

In simultaneous extension of all the coats of an artery, spontaneous cure is impossible, because it never arrives at the deposition of a clot (*c*).

[(1) The obliteration of an artery by the lengthening of an aneurysm into a pouch-like form, at that side of the sac most distant from the heart, is well explained by JOHN HUNTER. He says:—"Even in the last-mentioned situation, (the leg,) the force of the heart directs, in some degree, the swell of the tumour; but that is not until the sac is a good deal enlarged. The force of the blood against the most distant part of the sac endeavours to carry it on further in the direction of the motion of the blood, which in time makes a pouch; therefore it is elongated in the direction of the sound artery. The sac often, by its increase, presses on the sound part of the artery, and becomes the cause of its obliteration, as I have seen more than once." (pp. 544, 45.) Of this kind of spontaneous cure there is a magnificent specimen in the Museum at St. Thomas's, in an aneurysm of the femoral artery, just below the *profunda*, which has formed a large long sac that has descended for several inches below its communicating opening, and has completely compressed the artery, which is full of clot even into the ham.

(2) There is in St. Thomas's Museum a very excellent example of a popliteal aneurysm, in course of cure by this proceeding; the clot in the aneurysmal sac is very close and solid, and through its centre is a track, less in diameter than the natural tube of the vessel, by which the blood has been conveyed to the leg, but which has been evidently fast diminishing. FORD's cases, presently to be noticed, appear to have been cured in this way. In the Museum of the College of Surgeons there is a globular axillary aneurysm, about an inch in diameter, filled with laminated clots, and the artery beyond it contracted.—J. F. S.]

1410. What has been said about the spontaneous cure of false aneurysm applies also to artificial assistance. For in general the cure of an aneurysm is only possible, in so far as a closing of the artery can be produced, or such a collection of the clot in the sac, as may withstand the pressure of the blood, and gradually contracts; the artery, however, remaining pervious.

(*a*) HODGSON, above cited, p. 114. (*b*) Ib., p. 118.

(*c*) SCARPA.

1411. After the obliteration of the trunk of the vessel the circulation is carried on in the limb, by the collateral branches, which enlarge considerably, and are connected with each other by numberless anastomoses. In many cases a more direct and manifest anastomosis of the vessels take place, so that after the closure of the principal trunk, the stream of blood at once passes by the neighbouring branches; in other cases, the collateral circulation is only undertaken by small numberless anastamoses (*a*). Upon the different ways in which the collateral circulation is produced, and partly also on the point of time when the vessel is examined, after the obliteration of the principal trunk, may depend *whether the collateral branches appear more or less, or even not at all, enlarged.* The frequent examinations, in which, after the obliteration of the principal trunk of an artery, the other arteries of the limb are found considerably enlarged, do not therefore contradict the equally true observations, in which this enlargement is not found (*b*).

1412. The remedies which have been proposed, generally, for the treatment of aneurysm, are, *rest and antiphlogistic treatment, the application of cold and contracting remedies to the swelling, the compression, and tying* of the aneurysmatic artery.

1413. Strict rest, lowering treatment, restricted diet, repeated blood-letting, even to the greatest degree of weakening, (VALSALVA's plan,) and the internal use of *digitalis*, are the only modes of treatment by which the cure of internal aneurysm may perhaps be effected; in which indeed, under great diminution of the circulating power, the blood coagulates in the sac, and the aperture, whereby the sac communicates with the artery, is closed. In certain cases the area of the artery may be at the same time preserved, (*par.* 1409,) but in others the coagulation of the blood extends into the atrery, and shuts it up. In true aneurysm, a diminution and contraction of the walls of the artery may thus be effected.

1414. The *astringent remedies* employed for the purpose of restoring their elasticity to the arterial coats, or for effecting the complete coagulation of the blood in the sac, are, applications of cold water, pounded ice (1), bark, oak bark, and so on. If this mode of treatment, which was formerly employed, have in many cases a satisfactory result, it may be in part ascribed to the compression generally at the same time employed with it, and more especially to keeping the patient at rest. Perhaps, however, all share in the business must not be denied to these topical applications, as they are capable of favouring the coagulation of the blood in the sac, and in this way promoting the cure (*c*).

[(1) GUÉRIN, of Bordeaux, appears to have first proposed the application of pounded ice, or iced water, to the aneurysmal sac (*d*); and though its beneficial use was much doubted, yet RICHERAND says, that "subsequent observations have proved the advantage of pounded ice in the treatment of aneurysm. The examinations of the bodies of persons cured in this way, have dissipated all doubts as to the value of this remedy." And he mentions a case reported in the *Bulletin de la Faculté de Médecine de Paris*, No. 4, 1812, in which a popliteal aneurysm was thus cured. The patient lived a considerable time after the disappearance of the tumour, and the preparation is now in the Museum of the School of Medicine. On the contrary, HODGSON says:—"I have seen ice applied to a large inguinal aneurism, but it produced such excruciating pain that its employment was from necessity discontinued." (p. 163.)]

1415. *Compression* and *ligature* of the aneurysmatic arteries are the two modes of treatment which especially apply to the cure of external aneurysms. They agree with each other in effecting the obliteration of the artery; this takes place slowly by compression, in which case the circulation is gradually restored by the collateral branches, but occurs quickly on tying the artery. Only in a spurious aneurysm, which arises from a wound in an artery, and has not long existed, can a cure by compression be effected, without subsequent closure of the artery, as has been already granted in wounds of arteries, under certain circumstances (*par.* 279.)

1416. Compression has been employed *upon the aneurysmal swelling, above it, and as a swathing of the whole limb.* Proper apparatus or bandages have been used for the purpose.

1417. *Compression of the swelling alone*, is on many grounds objectionable. It is difficult or impossible, on account of the depth of the artery, and the different size of the swelling, always to employ the compression properly, and in the same direction; the aneurysmal sac may be developed in another direction, and if the compression be made sufficiently great, severe pain, inflammation, and bursting of the sac, may be caused. Nor is it certain whether the pressure operates upon that part of the artery above the opening, by which the sac communicates with the artery, or upon the part below this opening, in which latter case the speedy bursting of the artery may be produced.

1418. Compression of the artery is to be made at that part above the aneurysmal swelling, where the artery is superficial and the surrounding parts afford a proper point of support for the compression; in doing this, however, care must be taken to avoid the collateral vessels above the swelling, especially the larger ones. All the contrivances by which this compression is effected, must be so managed that they compress the limb only on two sides, because otherwise they would check the circulation too much (*par.* 285.) The compression must be gradually increased, with the greatest care, and so long continued till the obliteration of the artery is effected. This compression is often unbearable, when, for example, the artery is accompanied by the principal vein of the limb, or by considerable nerves. The femoral artery in its upper third, and the brachial artery, throughout its whole length, bear compression best. The position of the median nerve, however, close to the brachial artery, renders this less fitting, and the compression is painful. It is therefore especially applicable only to the femoral artery (*a*).

Here also may be mentioned alternate compression with several tourniquets at different parts.

Hutton and **Cusack** (*b*) have communicated cases of successful result from compression of the femoral artery in aneurysm of the popliteal artery, in which the compression was employed only for some hours, and repeated every day, or at longer intervals.

1419. The *compression of the whole limb*, by proper bandaging, in which, by the application of graduated compresses along the course of the artery, increased pressure is made, is not usually accompanied with inconvenience to the patient; the œdematous swelling disappears, and the cure may be effected by this simple remedy. The event of the cure in these cases appears always to be the complete coagulation of the blood in the

aneurysmal sac, depending on the arrest of the circulation throughout the whole limb.

[The unsatisfactory results of the treatment of aneurysm by tying the affected artery above and below the sac, opening and emptying the latter, either before or after the ligature, and then inducing it to fill up by granulation, as also the dangers of amputation, led GUATTANI (*a*) to consider the possibility of some other proceeding for the management of "a disease, so evidently incurable, that both medicine and surgery renounced all kind of treatment." He had, however, observed several cases spontaneously cured, in patients who would not submit to either of these operations, and he hoped to succeed by a somewhat similar process. "Many indeed," says he, "were the trials and dangers depending on the varieties of aneurysm, some of which differed from others in their nature; nor did all arise from one and the same spot. But when I especially inquired into those aneurysms which occurred at joints, I was led to suspect that by rest in bed and weakening the whole body, at the same time also restraining the flow of blood in the artery running to the affected part, and finally by gradually compressing the aneurysmal tumour itself by the aid of bandages, I might be able not only to prevent its increase, but that in course of time the grumous blood would, by little and little, of itself, be changed into serum, and rendered fit for circulation, and that the entire resolution of the tumour would at length take place. A methodical bandaging, which should from day to day more and more compress the affected part, seemed to me the only means which could fulfil all the indications; but as in doing this many hindrances occurred to me which seemed adverse to a happy result, I continued in doubt, whether I should entirely give it up, or whether at some future time I should be induced to practise it." (p. 129.) In this frame of mind he continued till 1757, when a case of aneurysm of the upper part of the femoral artery having occurred, he employed simple bandaging, which to a certain degree controlled the growth of the swelling. But the patient would not submit to the necessary rest, and left GUATTANI for another Surgeon, who tied the artery, and, probably opening the sac at the same time, bound it up very tightly, and the man died of mortification of the limb on the third or fourth day. As this could not be considered a satisfactory trial of his plan, he determined on trying it in another case, a spurious aneurysm, as he calls it, of the popliteal artery, and of which he commenced the treatment in November, 1765, according to the following manner:—"Having for some days previously," says he, "applied lint dipped in vinegar and water, I covered the whole mass of the tumour with lint, and then applied two oblong pillows across each other, like the letter X, upon the centre of the swelling, in such a way that the upper ends of both embraced the knee above and the lower below; another oblong pillow, wetted with vinegar and water, was then applied along the whole length of the femoral artery to the groin, and moistened all the lint surrounding the knee and covering the whole extent of the thigh. I then employed a strong long bandage, three inches wide and no more, and having made the first turn upon the centre of the swelling, carried it around both above and below, in the usual way of bandaging the joint, and wound it round sufficiently to cover up and compress it equally. In the same way I bound the whole length of the thigh up to the groin, and in order to render it more secure, made a couple of turns round the trunk, and so completed the bandaging. I took special care that the first turn of the roller should not too much constringe the part, and was very cautious that the pressure should be equally kept up, so that every turn of the bandage covered the preceding one rather more than half its breadth; which indeed, in every surgical operation where this indication presents, should always be done." (p. 131.) Blood-letting, low diet, complete rest of the joint, and the application of spirits of wine, were ordered. "I left the bandage undisturbed," he continues, "as long as it performed its duty. If properly applied, it would remain for eighteen or twenty days. * * * In re-applying I always took care it should be put on somewhat tighter. I also directed moderate blood-letting, especially when either the leg or foot swelled in the least, which prevented the renewal of the bandage if by chance it became tighter than the patient could bear. Subsequently the lint and pillows were moistened with vinegar and water, that I might prevent too much heat of skin, which coming on might have delayed not a little the cure. By patient and assiduous use of this treatment I was delighted to find that the swelling, although it constantly preserved its hardness and pulsation, daily decreased more and more; so that, indeed, after three months, I had the great pleasure of seeing the patient leave the hospital perfectly cured. Nothing remained of it at the place of the torn artery but a callosity, scarcely the size of a large

---

(*a*) Quoted at head of Article in LAUTH's Collectio.

bean." (p. 132.) Such was the treatment GUATTANI adopted and continued to practise with success, and upon it has been founded the practice of others at a subsequent period.

JOHN HUNTER tried compression in one of his cases, but the patient could not bear it, and he was obliged to tie the artery.

In the beginning of 1802, BLIZARD (afterwards Sir WILLIAM) attempted compression of the femoral artery in a case of popliteal aneurysm, with the hope of effecting obliteration, in the following manner (*a*):—" The points of support for the instrument were the outer part of the knee and the great *trochanter*, a piece of steel passing from the one to the other: and to the middle of this a semi-circular piece of iron was fixed, which projected over the femoral artery, having a pad at its end moved by a screw, by turning which, the artery was readily compressed, and the pulsation in the aneurysm stopped, without any interruption to the circulation in the smaller vessels. But although the patient possessed unusual fortitude of mind, and indifference to pain, he was incapable of supporting the pressure of the instrument longer than nine hours; and when it was loosened, the pulsation in the tumour returned with unabated force. After a fair trial of this plan the man quitted the London Hospital; and his femoral artery was tied by ASTLEY COOPER in the following April, in the then usual way, with two ligatures and division of the artery between. He did well.

In 1807, FREER, of Birmingham (*b*), having witnessed two cases in which GUATTANI's treatment had been adopted, " does not hesitate to recommend the cure of aneurism to be attempted, in the first instance, by pressure, rather than by an operation, which frequently occasions death, even when the patient might have recovered, if left to nature alone." Compression may be applied either on the aneurismal tumour itself, or upon the sound artery above it. In those cases, where pressure has been hitherto applied, it has been upon the tumour itself; and though this mode of application has frequently been attended with success, it is by no means so likely to answer the intention of uniting the sides of the vessels, as when used on the sound part of the artery. From the result of those experiments I made upon the radial artery of a horse, I should recommend the pressure to be applied on the extremities, either by the assistance of SENFFIO's instrument, or in the following manner:—First, place a bandage moderately tight from one extremity of the limb to the other, then place a pad upon the artery a few inches above the tumour, that you may have a greater probability of its being in a sound state; then, with a common tourniquet surrounding the limb, let the screw be fixed upon the pad, having previously secured the whole limb from the action of the instrument, by a piece of board wider than the limb itself, by which means the artery only will be compressed when the screw is tightened; the tourniquet should then be twisted till the pulsation in the tumour ceases. In a few hours, as by experiment in the horse, the limb will become œdematous and swelled; the tourniquet may then be removed, and no stronger pressure will be required than can easily be made with the pad and roller. The irritation produced by this mode of pressure, excites that degree of inflammation of the artery which deposits coagulable lymph in the coats of the vessel, thickens them, diminishes the cavity and eventually obstructs the passage of the blood." (pp. 112,13.) HODGSON mentions two cases in which this mode of treatment was adopted: in the one, a popliteal aneurysm, the pressure could not be supported longer than two hours, and in the other, where " it was applied to the brachial artery, the pain and swelling of the limb was so considerable that the Surgeon was compelled to abandon the practice."(p. 177.)

RICHERAND (*c*) observes, that if " the compression be made above the aneurysm, the compressed artery must be superficial, and have a solid *point d'appui* in a neighbouring bone. The compression also must not operate on the whole circumference of the limb; if spread over too large a surface, it will be too weak to press down the walls of the vessel; it will uselessly cause severe pains, produce swelling of the limb, by opposing the return of the lymph and venous blood; and it will hinder the passage of the blood through the collateral vessels, and consequently tend to produce want of nourishment, and gangrene of the limb, by obliterating all its vessels, on which account circular compression is to be entirely discarded in cases of aneurysm. * * * A tourniquet, or any analogous instrument, should be used, which will make a strong pressure on a particular part of the artery, and at a part directly opposite; whilst the limb remains free from all compression at any other part of its circumference." In illustration of this method, he mentions a case of popliteal aneurysm, in which, for a whole year, complete quiet, lying in bed, low diet, bleeding every month, and pressure, where the artery passed through the tendon of the *m. triceps femoris*, were employed. " The compression was effected by a semi-circular steel spring, like that of a rupture truss; a screw, with a pad

---

(*a*) From a paper of ASTLEY COOPER's on Aneurism, in Med. and Phys. Journ., vol. viii. p. 2. 1802.

(*b*) Quoted at head of Article.

(*c*) Nosographie Chirurgicale, vol. iv.

at its end, graduated the pressure on the vessel at will. The pain at first prevented its constant application; but, by gradually accustoming himself to it, and increasing the force, he succeeded in weakening, and then in preventing the pulsations of the swelling, which became adherent, hardened, and reduced to a little tubercle, formed doubtless by the coagulated blood, and adherent to the inside of the aneurysmal sac. The practice of Professor DUBOIS presents many instances of success by the same means." (pp. 95, 6.)

Compression for the cure of aneurysm, has, however, been little thought of, or employed in this country, till within the last four years, when it was revived by HUTTON, of Dublin (*a*), for a case of popliteal aneurysm, as large as a hen's egg, as the patient would not submit to the operation of tying the femoral artery. "For three or four weeks he maintained the horizontal posture, and a compress and bandages were applied; but, as the tumour gradually increased in size, and as he suffered pain from the pressure, this treatment was discontinued." On the 1st *Nov.* 1842, HUTTON therefore applied an instrument, "so contrived as to admit of pressure being made by a screw and pad upon the course of the femoral artery, and the counter-pressure upon the opposite surface of the limb, without interfering with the collateral circulation. In the first instance, the compression was made upon the femoral artery in the middle third of the thigh; and, although it was effectual in compressing this vessel, it produced so much uneasiness that it could not be sustained, and, after a few applications, the apparatus was removed, and adapted to the upper part of the limb. *Nov.* 12. The femoral artery was compressed as it passes from the *pelvis* under POUPART'S ligament, and the pressure maintained for more than four hours. *Nov.* 14. The tumour feels rather more solid; the purring thrill before felt, on the re-entrance of the blood into the sac, is no longer sensible; the pulsation as before. *Nov.* 22. Duration of compression three hours; the pulsation returned after its removal. *Nov.* 24. Artery compressed six hours: same result. He could not bear pressure next day for soreness in the groin; and he had some pain in the tumour. *Nov.* 26. The compression resumed, and continued for four hours; when the instrument was removed, the pulsation had ceased in the tumour, which felt solid, and was free from pain. *Nov.* 27. The pulsation had in a slight degree returned; compression for six hours. *Nov.* 28. No pulsation was now felt in the tumour. It had decreased in size, and was solid. *Nov.* 29. The compression was maintained for six hours; no pulsation felt; compression applied three hours. *Dec.* 1. An artery, about the size of the temporal, is felt pulsating along the surface of the tumour, which is quite solid, much diminished in size, and is altogether free from pulsation. The use of the instrument was now discontinued. *Dec.* 27. The tumour reduced to the size of a small walnut, and very hard. He was this day discharged at his own request." (pp. 364, 65.) Very soon after the termination of this case, CUSACK treated a popliteal aneurysm in the same way, beginning first with a bandage over the whole limb, to which subsequently was added a compress on the aneurysmal sac; this was continued for a month, but without effect. "*Feb.* 22. HUTTON applied his instrument, the pad being screwed down on the femoral artery at as high a point as possible, and with a force sufficient to stop completely the pulsations in the tumour; a compress was then laid over the aneurism, and secured by a flannel bandage, beginning at the toes. He soon began to feel uneasy; but when it had been on for one hour and a half, his face became pale, his pulse weak and slow, and he complained of faintness, with a feeling of weight in the situation of the pad, running up to his heart, and a sensation of a rush of blood to his head, accompanied by profuse perspiration on the forehead and vertex; the instrument was now loosened, and he soon rallied. When quite recovered, the pad was again screwed down; but he could not bear it for more than half an hour at a time." The apparatus was continued for five days, the patient screwing down the pad as he could bear it; but no benefit having been gained, it was put aside, and a bandage applied. From the 22nd January to the 4th of March, he had been taking ten drops of tincture of digitalis thrice a day; but it was then increased to fifteen drops, which was continued a fortnight longer, and then left off entirely. "*March* 16. Sir P. CRAMPTON'S instrument, modified by Mr. DALY, was put on so as merely to lessen the impulse in the aneurism; no compress or bandage was put on the tumour. *March* 18. Bears this instrument much better than the last; has none of the unpleasant rush to the head. * * * No change in the tumour. *March* 22. The tumour is decidedly harder and smaller, the impulse being greatly lessened. At times there is only a thrill in the aneurism; sometimes there is no motion whatever in the tumour, even when the pressure is removed, but it returns on the slightest movement of the body. *March* 23. Pulsation has totally ceased; the tumour is very hard, and about the size of a large walnut; a large artery can be felt running down superficial to the aneurism, over which it can be easily rolled with the finger; it then divides into two

---

(*a*) Dublin Journal of Medical Science, vol. xxiii. 1843.

branches; the articular vessels do not appear enlarged. *March* 25. The instrument was removed to-day. The femoral artery can be distinctly traced as far as the opening in the tendons of the *triceps* and *vastus internus*. *April* 1. The tumour is decreasing; the enlarged artery above mentioned is much smaller than at the last report. *April* 7. Tumour continues to decrease; the entire artery can be traced until it enters the aneurism; but in the lower third of the thigh, and in the ham, the pulsation is so weak that it can only be felt on a careful examination. *April* 14. The enlarged artery has become very small, while the popliteal artery of the affected limb now pulsates as strongly as that of the sound one; a number of hard cords can be felt passing over the tumour." (pp. 367, 68.) In the spring of the same year (1843) BELLINGHAM (*a*) treated a case of secondary aneurysm of the right external iliac artery, which had been tied by him a twelvemonth before, and though the sac had suppurated and filled by granulation, reappeared on the 1st of *April*. He was kept perfectly at rest in the horizontal posture, from the 3rd of that month to *May* 11, five or six ounces of blood twice taken from the arm, and tartar emetic and digitalis given. About ten days after his admission, the integuments became a little discoloured. No further change, however, occurred: and, on *May* 11, pressure on the *distal side* of the tumour was made, by means of the instrument for compressing the femoral artery in popliteal aneurysm, was commenced; but it appeared rather to increase the pulsation in the tumour." The pressure was continued at intervals, and on the next day the pad was applied to the artery at the origin of the *profunda*. The pressure was kept up the following three days, but discontinued at night; the tumour was smaller, and its pulsation diminished, but after a few days became more perceptible, and the apparatus was therefore left off." Some days subsequently, pressure was applied directly upon the tumour, by means of a compress, adhesive plaster, and bandage tightly round the body." After some days the tumour had diminished in size, and became more flat; the pressure gave no uneasiness, and was continued till the beginning of July, and on the 20th of that month, "some remains of the tumour could still be detected by pressure over its side, but no pulsation or bruit of any kind could be heard; neither can any pulsation be felt in the femoral artery, from POUPART's ligament downwards. *Aug.* 17. No tumour can now be felt; there is merely a little hardness in the situation of the former swelling" (p. 243-6.) In 1844, in another case, which was a femoral aneurysm in a man, who, fifteen months previously, had had popliteal aneurysm of the other limb cured by pressure, BELLINGHAM, after one bleeding from the arm, and fifteen drops of tincture of digitalis for five days, applied the same kind of instrument as that which had cured the disease in the other limb, at the groin, relaxing it at intervals when the pressure became painful. On the third day the instrument, having got out of order, required removal, and was temporarily replaced by a tourniquet pad at the groin, upon which a four-pound weight was placed, and this, with a slight pressure of the patient's hand, stopped the pulsation. On the following day a seven-pound weight was substituted, the tumour was somewhat more firm, and rather diminished in size; but the pulsation was still very strong when the pressure was removed. Ice was applied a day or two after to relieve the heat felt in the evening. On the eighth, a bandage was applied round the limb, from the toes over the tumour, and partly up the thigh, and the original pressure apparatus again put on; but on the twelfth day the weight was resumed, as the patient preferred it. On the nineteenth day, the pressure having been kept up steadily, except at night, whilst he sleeps, "the tumour is evidently more firm, and smaller; the patient suffers no pain when it is pressed or handled, and has lost the uneasy feeling about the limb. To-day an instrument, in form of a carpenter's clamp, was applied, the pad of which was fixed upon the artery in the upper third of the thigh, and he retained it on for several hours. However, as it compressed the femoral vein also, the limb swelled, and he was obliged to remove it towards evening." The pressure was continued on the same principle, but with an improved instrument for the following seventeen days, but the tumour continued stationary. On the thirty-sixth day a second similar instrument, "but with a larger arc, so as to permit the pad being placed over the artery in the groin, was applied, and the patient directed to use it alternately with the other upon separate portions of the vessel; and, when the pressure became painful at one point, to tighten the screw of the other, and then relax it. About three in the afternoon, he fixed the pad of one instrument on the femoral artery, where it passes over the horizontal *ramus pubis*, and the second on the femoral artery lower down, and continued the pressure nearly constantly up to twelve o'clock at night, when, on relaxing the screw, he found that the pulsation of the aneurism had ceased. He, however, persevered in the use of the instruments throughout the night." On the forty-second day, the pulsation had entirely ceased;

(*a*) Dublin Journal, vol. xxvi. 1845.

"a vessel of some size was now, for the first time, felt, which ran superficially in the course of the femoral artery, and had evidently become enlarged since the filling up of the sac of the aneurism. The patient says that last night, about twelve o'clock, when he loosened the screw of the instrument, the aneurism no longer pulsated, from which time he suffered much pain, both in the tumour and about the knee." These symptoms, however, subsided on the following day, when, "in addition to the superficial artery already mentioned in the course of the femoral, the articular arteries about the knee were found enlarged, one of which, on the inside, is nearly as large as the radial artery." On the fifty-seventh day "the tumour was about the size and shape of a small hen's egg, very firm and solid. The pulsation in the femoral artery can be traced from the groin to within a short distance of the obliterated sac of the aneurism." (p. 248–54.)

Such are the results of the first three cases, in which aneurysm has been treated by compression by the Irish Surgeons, and **Bellingham** has enumerated (*a*) nine other cases in which it has been employed, three of which have been managed in England by **Liston**, **Allan**, and **Greatrex**, and the rest in Ireland, and all cured. Thus **Crampton**'s assertion (*b*), that "intermediate compression, or compression from without (maintained for a sufficient length of time to allow the blood in the aneurismal sac to coagulate) had been tried and was found ineffectual," (p. 359,) is proved to have been so only on account of the inefficient mode of the application of external pressure. From this account, although I have yet had no opportunity of practising this treatment, I must confess I think it highly worthy of serious attention, and am much disposed to think I should try it on a fitting occasion. **Bellingham** very justly observes, upon the advantage of alternating pressure upon the artery, that "the principal improvement which has taken place in the treatment of aneurism by compression, consists in the mode of applying the pressure; that is, instead of employing a single instrument, we employ two or three, if necessary; these are placed on the artery leading to the aneurismal sac; and, when the pressure of one becomes painful, it is relaxed, the other having been previously tightened, and, by thus alternating the pressure, we can keep up continued compression for any length of time. By this means the principal obstacle in the way of the employment of pressure has been removed; the patient can apply it with comparatively little inconvenience to himself; time will not be lost owing to the parts becoming painful or excoriated from the pressure of the pad of the instrument; and, as the pressure need not be interrupted for any length of time, the duration of the treatment will be necessarily considerably abridged." (p. 167.) With regard to the treatment of the artery which has been thus treated, **Bellingham** says:—"It will be observed, from the histories of the cases which have been published, that the femoral artery could be traced, after the cure, to near the sac of the aneurism, proving that the artery is never obliterated at the point compressed." (p. 165.) This is a very interesting circumstance, and supports **John Hunter**'s opinion, that "the force of the circulation being taken off from the aneurismal sac, the progress of the disease would be stopped."]

1420. As regards the more precise determination of making use of pressure for the cure of aneurysm, it is advised by many to employ it in all aneurysms, so that even if no cure take place, a progressive expansion of the collateral branches may be effected. It may be employed if the aneurysm be still recent, if it be not large, especially when the consequence of an external injury; if there be no circumstances which render a speedy cure necessary; if the patient be not very stout, the limb not very much swollen, and the artery so situated, that its walls can be properly brought together by compression. Where beneficial, it soon shows; the experiment of compression is, therefore, never to be persisted in too long, and it should be left off as soon as circumstances occur which may render it dangerous. It is always proper to accompany the pressure with rest, blood-letting, cold applications to the swelling, and the internal use of digitalis, and so on.

Samuel Cooper (*c*) believes, that compression is successful only in about one out of thirty cases, and that a certain number of the successful cases must doubtless be considered rather as spontaneous cures of aneurysm.

(*a*) Med.-Chir. Trans., vol. vii. (*b*) Dublin Journal, vol. xxvii. 1845.

(*c*) First Lines of Surgery. London, 1819. vol. i. p. 304.

1421. *Tying* the aneurysmal artery (the *Operation for aneurysm*) is the most certain mode of treatment; and there are two modes in which it is performed. The one, laid down in the ancient Greek Surgery, by Philagrius and Antyllus, which consists in opening the aneurysmal sac, removing the coagulated blood, and tying the artery above and below it; the other, where the artery is laid bare and tied above the swelling, between it and the heart, upon which the swelling diminishes and disappears (1).

(1) This mode of operation is usually called the Hunterian. Although it had been previously practised by Anel (*a*) and Desault (*b*), it was, however, first raised to a systematic operation by Hunter (2). In former times, indeed, tying the brachial artery above the aneurysmal sac was performed by Aëtius, Paulus Ægineta, Guillemeau, and Thevenin; subsequently, however, even the sac itself was opened.

[(2) The operation of tying the artery at a distance from the aneurysmal sac, and where its coats are healthy, has been justly claimed by English Surgeons, for John Hunter, notwithstanding that till within a few years our French neighbours have laboriously endeavoured to show that it was merely a repetition of the operation performed by their countryman Anel, at Rome, in January, 1710, and subsequently by Desault, in June, 1785. Honourable exception to this nationality is offered by Deschamps' able vindication (*c*) of Hunter's originality in reference to his operation; and within the last few years his title to it has been almost universally conceded. The circumstances, however, are so interesting in reference to this operation and its importance so great, that a short notice of the operations of Anel and of Desault cannot be here misplaced.

Anel's operation was performed on the brachial artery of a friar which had been wounded in venesection, but which did not bleed till the fifteenth day after the injury, when it was checked by the use of astringents and bandage. Anel's account of the disease is exceedingly confused and probably he did not very well understand its true nature, for, he says:—"From the day of venesection to that of the operation, we see that three kinds of aneurysm have occurred in the same artery of the same arm," a true aneurysm, a false one, and a true one again, upon which last he operated. It is probable, however, that during the whole course of the disease it was none other than the ordinary spurious aneurysm following a wound in an artery, which, John Hunter (*d*) observes, "will produce various effects according to the treatment, all of which are called so many aneurisms: but I do not consider a wound in an artery, an aneurism, even if in an aneurism itself." (p. 543.) Anel thus describes the operation performed on the 30th January, 1710:—"Having made myself master of the blood by means of a tourniquet, I made an incision in the integuments without touching, in any way, the aneurismal sac; I then sought for the artery, which I found situated below the nerve, which is not common. I took every precaution in separating it from this, and having lifted it upon a hook, I ligatured it *as near to the tumour as possible*. The artery having been tied I loosened the tourniquet, when a small muscular branch, which I had divided in dissecting the vessel, bled and compelled me immediately to tighten the tourniquet and to tie the artery again a little higher up; the tourniquet being loosened, I saw no more bleeding nor any pulsation in the tumour. I then applied the proper dressings and a bandage." (p. 220.) On the following day pulsation of the artery at the wrist was very distinct. "The first ligature separated on the 17th day of February, 1710; and the second on the 27th of the same month; without the supervention of the least hemorrhage, on the 1st of March in the same year, this friar not only left his room, but went even to church. * * * On the 5th of March the wound was perfectly cicatrized." (p. 221.) In his reflections on the case, Anel observes:—"With regard to the mode of doing the operation, I performed it in a different way to what authors describe, which I have seen good Surgeons adopt, and which I have myself had recourse to several times; for instead, as is customary, of applying the ligature above and below the aneurism, I only practised it above. Besides, the aneurismal sac is usually opened, but I did not touch it at all; not doubting but that the blood contained in it would be dissipated, being at

(*d*) Lectures on the Principles of Surgery; in his Works, edited by Palmer.

liberty to pass on towards the extremity; that the sac, being once empty, would not fill again; that the layers of membrane that formed it would not fail to collapse; and that thus the tumour would disappear, all which happened as I thought. In this way the operation was less tedious, and much less painful; besides, my incision was not half the usual length, hence there was a smaller cicatrix." (p. 223.) The tumour collapsed in such a way that it would have been impossible to have ascertained the spot where the aneurism existed." (p. 222.)

Desault's operation, as stated by Sabatier (*a*), was performed in June, 1785, upon a popliteal aneurysm which "had acquired the size of a turkey-hen's egg; the patient was thirty years of age. * * * Desault made an incision about two inches in length at the upper part of the tumour, laid the artery bare, separated it from the nerve and tied it. * * * On the sixth day he tied a ligature of reserve, that he had placed under the artery above the first one. The state of the wound and of the patient was such as to promise a speedy cure." The tumour diminished to half its size and the ligature came away on the eighteenth day. "On the following day the wound discharged a tolerable large quantity of matter mixed with blood, and the tumour disappeared almost entirely; an evident sign of the rupture of the aneurismal sac. After this nothing was left but a fistulous opening which healed in a few days." (p. 403.)

Erichsen (*b*) observes:—"From the following remark by Maunoir it would appear that little importance was attached to the operation at the time even by Desault himself. 'I lived,' says Maunoir, 'two years with Desault, and I do not remember to have ever heard him speak of this operation. It had not been considered of consequence; and in general, it seemed to me, that it was quoted without being understood and after very vague reports.'" (p. 403.)

Desault's operation was also performed by Pott after Hunter had performed his new operation, in a case of femoral aneurysm of which E. Home gives a brief and not very clear account in the paper presently to be cited from; it did not, however, succeed, and amputation became necessary, at what period, however, Home does not state.

I have heard it mentioned that John Hunter was indebted to Ford, for the suggestion at least, if no more, of his mode of operating in cases of aneurysm. It is not at all improbable that Hunter's mind may have been led to the operation he afterwards practised, from his reflection on the two cases of Ford's, presently to be mentioned; but this appears to be all Ford had to do with the matter, as it is very unlikely he should not have taken notice of the subject, had he any claim to it, in the paper (*c*) he published between two and three years after Hunter's first operation; and, in fact, he utterly discourages any kind of operation. He says:—"An aneurysm of the larger vessels, when it occurs in the trunk of the body, is a disease that is usually fatal, and it is not uncommonly so when it happens in the extremities; the mode of cure in the latter case, whether by amputation of the limb or by tying the artery, being universally allowed to be hazardous. * * * The cases I now communicate to you serve to establish the fact, that in cases of aneurysm the efforts of nature alone, unassisted by art, have produced in the coats of the vessel a coalescence of its sides, firm enough to render the artery impervious to the impetus of the blood, whilst the circulation in the extremity has been amply supported by the collateral branches going off above the aneurysmal tumour." (pp. 142, 43.) The first case he met with, several years previous to publishing his paper, was a popliteal aneurysm in a chairman. "He was admitted into an hospital, and at the end of three months, when he called upon me," (again,) says Ford, "I found that the tumour had totally disappeared, and that the limb was wasted, and a little weaker than the other, but that he was capable of doing his business. Upon inquiry, I could not learn that the cure could be ascribed to any other means than to the efforts of nature, with which an horizontal position of the body, and a regular diet, might perhaps have co-operated. This man died soon after of a fever, and as the limb was not examined by dissection, and a doubt arose whether the tumour was aneurysmal or not, the circumstances of the case were not deemed strong enough to justify any inference to be made from it." (pp. 143, 44.) The next case was that of a clothes-presser, thirty-six years of age, who had "a tumour situated on the anterior and upper part of the right thigh, about three inches below Poupart's ligament. It was of the size of a turkey's egg, and had a strong pulsation." He had also, "at the same time, a swelling about the size of a pullet's egg in the ham of the other leg, in which was felt a tremulous pulsation." (p. 144.) Two months after, the swelling in the right thigh had considerably increased; and from the irritation, probably dependent on a

(*c*) Cases of the Spontaneous Cure of Aneurism, with Remarks; in London Medical Journal, vol. ix. 1788.

mustard poultice having been applied, and a cordial regimen directed by an empiric to promote suppuration, he had a very severe attack of fever, which, however, by proper treatment was relieved. No operation was proposed for fear of mortification and fatal hæmorrhage. "We now examined the other leg," says Ford, "but found no traces left of the swelling I had formerly seen." Six weeks after he died with gangrene of the right thigh, without hæmorrhage. On *examination* of the left ham, "externally there was no mark left of the tumour; but upon cutting down to the vessel, we found the popliteal artery enlarged to the size of a small hazel nut. On opening the artery, both above and below this tumour, and endeavouring to pass a director and a probe, it was found to be quite impervious to the instruments, although some force was used; and upon further examination, it was found plugged up by a substance of a hard and firm consistence." (p. 148.) The last case was a femoral aneurysm, seen by Ford in September, 1785, when it "was about the size of a middle-sized China orange, and obviously increasing. The situation of it was so high up as to admit of no hope of preserving his life by removing the limb, or by tying up the artery. It was, therefore, only recommended to him to lie in bed, to keep his bowels open by gentle laxatives, and to live upon a very spare diet." (p. 149.) Among the professional people who saw this man, and by whose concurrence compression at the groin was made, but could not be persevered in on account of the severity of the pain, Hunter is mentioned; but this case could not have encouraged or induced him to perform his new operation, because "for four months (from September) those symptoms continued to prevail which usually precede a fatal termination," and it was only "at the end of six months that the man began to think the pulsation was not so strong in the swelling, and that it had ceased to increase. * * * In the month of March, (three months after Hunter had operated on his patient,) the circumference of the tumour was much lessened, and the pain had ceased; the tension was also diminished, the inflammation of the skin had given way, and was now become scabious, putting on a mottled look, and appearing in some parts brown, and in others of an orange colour. (pp. 150, 51.) For two months afterwards the tumour continued to lessen. * * * He was sent into the country, where he soon recovered his strength and the use of his limbs so much, that in three months he was able to walk several miles with a stick." After the lapse of two years, he was fully recovered; but "the thigh was two inches and a half in circumference larger than the other, and there was a hard incompressible tumour where the aneurism was, but which gave him no uneasiness." (pp. 151, 52.) From this account, it is quite clear that the second is the only case which could at all have attracted the attention of such a mind as that of Hunter, and lead to the proposal of his operation; but neither of the three seemed to have impressed Ford beyond the importance of quiet, and its adequacy to effect the natural cure of the disease; and from his review of these, as well as of the cases recited by Guattani, he infers—"1st. That nature is capable of effecting the cure of many aneurisms solely by her own efforts. 2nd. That these efforts have been successful even when counteracted by improper treatment, as in the (second) case of the popliteal aneurism (no mention, however, is made of such improper treatment in the recital of the case. J. F. S.); but that a quiet position of the limb, with an antiphlogistic regimen, contributes to the cure. 3rd. That the cure by nature is a permanent one. 4th. That the inert mass left behind is not likely to produce any mischief. 5th. That the unsuccessful event of the operation for the popliteal aneurism, does not principally depend on any particular hazard in consequence of an obstructed circulation in the ham, but upon other causes." (p. 155.)

The first notice of John Hunter's improvement in the operation for aneurysm, was given by Everard Home in the year 1786 (*a*), and in that subsequent, the dissection of the case. He also published another paper (*b*), giving the history of all the cases on which Hunter operated, together with some by other Surgeons. In the first paper Home introduces the case with the following remarks:—

"The common method of operating in cases of popliteal aneurism having, in many instances, proved unsuccessful, the operation itself has been condemned by some of our most eminent Surgeons. If we consider the cases in which it has been performed, and where the patients have died, we shall probably find that in all of them the artery had been diseased at the part enclosed by the ligature, and had either sloughed off, or had been cut through where it was tied, so that the sides of the artery, though brought together, had not remained a sufficient length of time in that situation to unite by the

---

(*a*) An Account of Mr. Hunter's Method of performing the Operation for the Cure of the Popliteal Aneurism; in London Medical Journal, vol. vii. 1786, vol. viii. 1787.

(*b*) An Account of Mr. Hunter's Method of performing the Operation for the Cure of the Popliteal Aneurism, containing all the cases on which he had then operated; in Transactions of a Society for the Improvement of Med. and Chir. Knowledge, vol. i. 1793.

first intention, and the patients lost their lives from the consequent hæmorrhage. The femoral and popliteal arteries are portions of the same trunk, presenting themselves on different sides of the thigh, and are readily come at in either situation; but where the artery is passing from the one side to the other, it is more buried in the surrounding parts, and cannot be exposed without some difficulty. In performing the operation for the popliteal aneurism, especially when the tumour is large, the ligature is commonly applied on the artery at that part where it emerges from the muscles. This will be too limited a space, should it prove diseased for some way higher up; and if the artery should afterwards give way from any of the causes above mentioned, there will not be a sufficient length of vessel remaining to allow of its being again secured in the ham. To follow the artery up through the insections of the *triceps* muscle, to get at a portion of it where it is sound becomes a very disagreeable part of the operation; and to make an incision on the fore part of the thigh, to get at and secure the femoral artery, would be breaking new ground—a thing to be avoided, if possible, in all operations. From these considerations, suggested by the accident of the artery giving way, which happened several times to Mr. HUNTER, he proposed, in performing this operation, that the artery should be taken up at some distance from the diseased part, so as to diminish the risk of hæmorrhage, and admit of the artery being more readily secured, should any such accident happen. The force of the circulation being thus taken off from the aneurismal sac, the cause of the disease would, in Mr. HUNTER's opinion, be removed; and he thought it highly probable that if the parts were left to themselves the sac, with the coagulated blood contained in it, might be absorbed, and the whole of the tumour removed by the actions of the animal economy, which would consequently render any opening into the sac unnecessary." (p. 391–93.)

1422. The operation for aneurysm is generally indicated—1. If compression be not applicable. 2. When, as regards the position of the artery, it can be employed, but cannot be borne. 3. When the aneurysm, already large, threatens to burst, or has burst. 4. In spurious diffused aneurysm, when the effusion of blood is considerable. The result of the operation for aneurysm is extremely doubtful, if several aneurysms exist in the same person, if the patient be in years, or weakly, if from the size of the swelling, destruction of the bones and neighbouring parts have been produced, whereby, perhaps, the collateral branches have been closed; if the arterial coats be rigid, or in any other way changed by disease, and compression, by swathing the limb, have been too long employed. The larger the principal trunk to be tied is, the more doubtful is the *prognosis;* the assistance rendered by nature by the enlargement of the collateral circulation is, however, very remarkable, and under the most unfavourable circumstances the treatment often presents the happiest results.

[E. HOME has justly observed, "that Surgeons have laid too much stress on the necessity of large collateral branches being present, to ensure the success of this operation; this must have arisen more from their anatomical knowledge, than from observations made from practice, since we find the trunk of the femoral artery may be taken up in any part of the thigh, without producing mortification of the limb. In one patient afflicted with aneurism, whose limb Mr. HUNTER examined after his death, though there was great reason to believe that the artery had been obliterated above the great muscular branch, the limb had been very well nourished." (p. 399.)

As regards the size of an aneurysm, best suited for operation, JOHN HUNTER says:— "I wish never to see one, that can be made the subject of an operation, larger than a walnut before it is operated on." (p. 543.) Surgeons however, at present, rarely care about the size of an aneurysm, provided the skin be healthy, and there be sufficient space to apply a ligature between it and the heart, on a presumed healthy part of the artery.—J. F. S.]

1423. In the operation for aneurysm, *by opening the sac*, after the circulation into the artery is arrested by the application of a tourniquet above the aneurysmal part, the skin covering the swelling is to be divided by a cut, which must extend from above to below it; the sac of the aneurysm is to be opened in the same direction, all the blood-clot removed, and the cavity cleansed. The Surgeon then endeavours to find out the proper opening of the artery, introduces into it a probe or a female catheter, with which the artery is to be raised above the sac and separated from the surrounding parts; a ligature is then to be passed round it with Deschamps' needle (1) and tied. In this way the artery is to be isolated and tied above the swelling. (What will subsequently be said, in reference to the form of the ligature, applies here.) The cavity of the sac is then cleansed, filled lightly with lint, covered with sticking-plaster and a compress, and the whole kept in its proper place with a four-headed bandage.

(1) Deschamps' needle is the most convenient instrument for a ligature; if made of silver, it can assume every necessary curve. Weiss's and Kirby's needles are suitable for some cases of very deep-lying arteries.

As to the numerous varieties of aneurysmal needles, compare—

Arnemann, Uebersicht der berühmtesten und gebräuchlichsten Instrumente älterer und neuerer Zeit. Göttingen, 1796, p. 193.

Krombholz, Akologie, p. 391.

Holtze, De arteriarum ligatura. Berol., 1827. 4to., pl. ix.

1424. Hunter's mode of operation requires the laying bare and isolation of the artery at a suitable distance above the seat of aneurysm (1). It is here especially to be remembered, that the artery should be separated from its surrounding cellular sheath only as far as is necessary to carry around it, with Deschamps' needle, a round, but not too thick ligature, which is to be firmly tied upon the artery with two single knots (2). The ends of the thread should be laid in one or other angle of the wound, the edges of which are to be brought into close contact with sticking-plaster, in order to effect the cure, if possible, by quick union. The ligature separates, according to the size of the artery, between the eighth and sixteenth day.

I consider tying the artery with a single round ligature, by which its inner and middle coats are divided, (ascertained by the artery forming a swelling above and below the ligature, and by the ligature being heaved up by the impulse of the blood,) with the simultaneous simple treatment of the wound, as the most preferable mode of treatment (*pars*. 283, 285.) The different modifications must, however, be here mentioned, which have been proposed for the more certain attainment of a successful result.

Scarpa (*a*) holds, in opposition to Jones, (who concludes from his own experiments, that the division of the internal coat of the artery, with a single round ligature, favours the formation of a plug of blood, the adhesive inflammation, and the pouring out of plastic lymph within and without the artery,) that this result happens less frequently in men than in animals, that after-bleeding occurs the more quickly, as on the setting up of suppuration, the external coat of the artery is less capable of withstanding the impulse of the blood, and that this happens so much the earlier, as the division of the arterial coats by the ligature-thread resembles more a torn and bruised, than a cut wound. Also that the ligature-thread does not bring both the divided coats together, but only the wrinkled walls of the external. As the internal coat of the artery is very much disposed to adhesive inflammation, and plastic exudation, so a pressing together of the artery is sufficient to bring about adhesion. Upon these grounds, Scarpa prefers, to all other modes, tying the artery with a small band of waxed threads, between which and the artery, a little linen cylinder, smeared with cerate, is placed. In this mode, however, the artery must be laid bare, no further than necessary to carry the band round it, nor the cylinder be longer than a line, or thereabouts, beyond the ligature, which, for the largest artery, should be about a line. The band must not be drawn excessively, but only sufficiently tight to keep the uninjured walls in close contact. By this plan of tying, a closure of the artery is produced by the actual joining together of the touching walls of the artery. Such flattening of the artery and touching of its walls, had been previously performed with broad ligatures, with the underlaying of a piece of wood or cork (3). Deschamps (*b*), more recently Crampton (*c*), Assalini (*d*), and Köhler (*e*) have

(*d*) Grossi.

(*e*) Dissert. sistens quædam de Aneurysmatibus scalpelli opera curandis. Berol., 1818.

attempted to operate with peculiar arterial compresses; these metallic contrivances are, however, dangerous, and in reference to their operation on the coats of the artery, and the parts surrounding it, not comparable to the soft cylinder which adapts itself to the periphery of the artery.

Jones (*a*) advanced the opinion, that, if upon a large artery several circular ligatures be made near each other, whereby as many tears of the internal coat are produced, and the threads be immediately removed, the plastic lymph effused into the cavity of the artery is sufficient for its obliteration. Hodgson (*b*) has, by experiment, disproved this opinion. Travers (*c*) recommended, but subsequently disadvised such treatment. Cases, however, are given, in which the ligature was removed twenty-four hours (*d*), and fifty and a half hours (*e*), after tying, and the cure ensued. Scarpa also has observed, that the closure of the artery follows, if the ligature, with its subjacent linen cylinder, be removed on the third or fourth day; only in weakly persons is it necessary to leave the ligature till the sixth day. Scarpa, as well as others, have made known cases favourable to this mode of treatment. His mode of applying the ligature with a subjacent cylinder specially facilitates its removal. Scarpa uses a peculiar grooved probe, cleft in front and open, and a small knife for loosening the ligature. The proposals of Palletta and Roberts must be here mentioned; by means of a sliding thread, the tightened principal loop may be again loosened; by Giuntini, one thread is attached to a little roller, in order to draw it out after the loop is cut through; Uccelli introduces a small metal half cylinder between the linen roller and the loop (*f*). Vacca Berlinghieri (*g*) is in favour of Scarpa's mode of tying with the linen roller, but not for the removal of the ligature on the fourth day. The experiments, as regards the temporary ligature on the human subject, are not yet sufficiently numerous to decide whether it should be generally employed, or only in particular cases, perhaps in old subjects and so on. It is always to be remembered, that the removal of the roller acts as an interruption, for it is firmly pressed on the artery by the loop, clings tight to it, and cannot be removed without tearing, even after the loop has been cut through. In order to get rid of the inconvenience dependent on the threads hanging out of the wound, Lawrence (*h*) proposed tying the artery with a fine silk thread, cutting it off at the knot, and closing the wound, (for the same reason, Astley Cooper (*i*) used silk-worm gut previously moistened in warm water,) as the retained knots are either absorbed or enclosed in a cellular capsule. Many cases, however, decide against this mode of tying (*j*). Maunoir (*k*) and Abernethy (*l*), under the supposition that the tied artery retracts actively, and thereby especially produces tearing and secondary bleeding, advised the application of two ligatures, and the division of the artery between (4). The rarity of secondary bleeding after amputation, which has been considered as a reason for the preference of this mode of tying, is on more than one ground inapplicable; experience is opposed to this method of tying; besides, in many cases, it cannot be undertaken, on account of the want of space, or the deep situation of the artery. The application of the so-called reserve ligature, that is, some threads which in case of secondary bleeding may be drawn together, is not only useless, but dangerous, and therefore to be rejected.

[(1) The operation of tying the femoral artery, for popliteal aneurysm, the first upon which John Hunter (*m*) operated by his new method, Dec. 1785, was conducted in the following manner:— "A tourniquet was previously applied but not tightened, that the parts might be left as much in their natural situation as possible; and he began the operation by making an incision on the fore and inner part of the thigh, rather below its middle, which incision was continued obliquely across the lower edge of the *sartorius* muscle, and was made large to give room for the better performing of whatever might be necessary in the course of the operation; the *fascia*, which covers the artery, was then laid bare for about three inches in length, and the artery being plainly felt, a slight incision, about an inch long, was made through this *fascia* along the side of the vessel, and the *fascia* dissected off, by which means the artery was exposed. Having dis-

engaged the artery from its lateral connections by the knife, and from the parts behind it by means of the end of a thin spatula, a double ligature passed behind it by means of an eyed probe, and the artery tied, by both portions of the ligature, but so slightly as only to compress its sides together; a similar application of ligature was made a little lower; and the reason for passing four ligatures was to compress such a length of artery as might make up for the want of tightness, as he chose to avoid great pressure on the vessel at any one part. The ends of the ligature were carried directly out at the wound, the sides of which were now brought together and supported by sticking-plaster and a linen roller, that they might unite by the first intention. * * * The fourth day, on the removal of the dressings, the edges of the wound were found united through its whole length, excepting where prevented by the ligatures. * * * On the ninth day after the operation there was a considerable discharge of blood from the part where the ligatures passed out; a tourniquet was therefore applied on the artery above, which stopped the bleeding; and although the tourniquet was taken off a few hours after, no blood followed. The head of a roller was now placed upon the wound, in the direction of the artery, and over that the tourniquet, which was not tightened more than was thought sufficient to take off the impetus of the blood in that portion of the artery. * * * On the fifteenth day some of the ligatures came away, followed by a small discharge of matter, and the tumour in the ham was lessened. * * * About the latter end of January, 1786, six weeks after the operation, the patient went out of the hospital, the tumour at that time being somewhat lessened, and rather firmer to the feel. He was ordered to make some degree of pressure, by applying a compress and bandage, with a view to excite the absorbents to action. * * * March the eighth, the wound which had cicatrized, broke out again, and the patient was taken into the hospital. About the eighth of April, some remaining threads of the ligature came away, and an inflammation appeared upon the upper part of the thigh. In the middle of May a small abscess broke at some distance from the old cicatrix, at which opening some matter was discharged, but no pieces of ligature were observed. Several small threads were, at different times, discharged at the old sores, and the swelling subsided; but the thigh soon swelled again to a greater size than before, attended with considerable pain. In the beginning of July a piece of ligature, about an inch in length, came away, after which the swelling subsided entirely, and he left the hospital the eighth day of July, at which time there remained no tumour in the ham, and he was in every respect well." (p. 394–98.) Among the few remarks which E. HOME makes on this case, he says:—" Mr. HUNTER now rather disapproves the application of a number of ligatures, in the manner practised in the above case, as these cannot come away without producing ulceration of the artery which they enclose, a tedious process when the ligature is not drawn tight; neither do I believe he would be again inclined to heal up the wound by the first intention, but rather to allow the cut surface to inflame and suppurate, by which he would have it more in his power to come at the artery, should that prove necessary; and probably, by means of the dressings, he might make a gentle compression to assist the ligatures." (p. 399.)

BIRCH (*a*), of St. Thomas's Hospital, performed, I believe, the second operation after HUNTER's mode, in a case of femoral aneurism, resulting from a blow. "On examination I found," says he, "a large tumour extending within two inches of POUPART's ligament upwards, and occupying two-thirds of the thigh; a pulsation could be felt, and there was no doubt of the disease being an aneurism of the femoral artery. * * * On Friday the third of November, (1786,) it was determined to perform the operation. Mr. CLINE undertook to compress the artery as it passed through POUPART's ligament, which he easily effected with a hard compress in the shape of a T with a broad basis. It was agreed previous to the operation, that an incision should be carried in a semicircular form round the upper part of the aneurismal sac, in order to make room for the longitudinal incision necessary to dissect down to the artery. This was accordingly done; and the integuments raised, so as to make room to feel for the pulsation of the artery. Some portion of cellular membrane and some lymphatic glands, were necessarily dissected and removed with my fingers. I then separated the muscular fibres, and tore away the connecting parts, till the artery could be plainly felt in pulsation. It was then necessary to divide a part of the *fascia* covering the artery, which was done by carrying the back of the knife on Mr. CLINE's nail, while his finger pressed upon the naked artery, after which the finger and thumb could surround and compress the vessel. An eye probe, armed with a strong flat ligature, was then pressed through the cellular membrane and carried under the artery. This being effected, we had such command of the vessel as to be able to strip it downward and pass another ligature

---

(*a*) London Medical Journal, vol. vii.; in HOME's paper just quoted.

somewhat lower. This last ligature was then tied, the first being left loose to secure us against accident. The threads being separated and secured, the wound was lightly dressed, the tumour left in its natural situation, and the patient put to bed with the loss of only four or five ounces of blood during the operation. No pulsation could be perceived in the tumour after the ligature was tied." (p. 401–403.) He went on well till the seventh day, when it is stated "the tumour grew thinner at one point and seemed as if disposed to ulcerate the integuments. On the evening of the eighth day he became feverish." On the tenth day "the tumour was very thin in one part, and a fluctuation evidently to be felt. The limb was warm and movable, but the patient was feverish and delirious at night." In this state he continued till the twelfth day, when he became sensible. "The tumour burst and discharged serum and grumous blood; he fainted; the dressings were not disturbed; he slept composedly; fainted again about six o'clock in the evening, and expired." (pp. 404, 405.) The examination after death, in this case, showed "the blood in the tumour very putrid, and the greater part of it fluid; it appeared to be dissolved by putrefaction. Water injected by the external iliac artery escaped freely from the wound at the ligature, where the artery was open, and appeared to have ulcerated at that part. In dilating the artery from the ligature to the heart, its internal surface appeared of a bright red. This appearance lessened at the curvature of the *aorta*, yet it was very evident in its semilunar valves. The *arteria profunda*, which passed off from the femoral artery rather less than half an inch above the ligature, was also inflamed within." There were nearly two inches of the femoral artery between the ligature and the aneurismal sac. (pp. 405, 6.) It may be here added, on Sir ASTLEY COOPER's authority, that the femoral artery in the space between the ligature and the *profunda* contained no clot, which he considered to have depended on the nearness of the latter artery to the ligature having prevented the formation of an internal clot, by the continuous flow of blood into that vessel. I am, however, by no means sure that this was really the case; it is very true that in the preparation which is in St. Thomas's Museum no clot is apparent, as the femoral artery is slit upwards from the ligature to its full extent; but it seems very probable that by the injection of the water that a clot might easily have been disturbed, and when the vessel was laid open that it might have dropped out unnoticed, as at the time of this case, such a circumstance was not much thought of.

(2) The importance of opening the sheath to the least possible extent, which its complete isolation and the application of the ligature, will admit, cannot be too strongly impressed. Nor less important is doing this with the least possible disturbance of the position of the vessel, which ought never to be lifted up nor dragged, as too frequently done. I think it is best after opening the sheath, to separate the artery gently with the director previous to passing the aneurysmal needle behind it. Some persons prefer DESCHAMPS' needle, the curve of which will be found to require adaptation correspondent with the depth and situation of the artery. Others prefer a blunt-pointed flexible silver needle without a handle, for the introduction of the ligature. I do not think it of much consequence which is employed; it is the dexterity and knowledge of the Surgeon, not the instrument that he employs, upon which the proper performance of the operation depends. Especial care should also be taken that no nerve be included in the ligature; and if the patient should express great pain at the time the thread is first tightened, there is good reason to believe this has been done, and it will be necessary to make a careful examination, and even loosen the knot, to be sure of the perfect isolation of the artery, otherwise dangerous symptoms will ensue. The size of the ligature should accord with that of the artery to be tied. As to the material, ASTLEY COOPER was accustomed to use Dutch twine, but round strong silk is generally employed, and its strength tested before it is applied, or it may break upon the artery in tying, an accident which I have witnessed more than once or twice. The artery should not be lifted up from its bed in making the knots, but the ends of the forefingers or thumbs carried down the wound to it, and then the tie made. Nor do I believe it needful to draw the silk so exceedingly tight as commonly recommended for the purpose, as it is said, of cutting through the internal coat; it should be drawn so much, that the whole of the internal coat be brought into close contact, and that the silk should indent the external coat of the vessel; in other words, the ligature should be tied moderately tight. I do not believe that cutting through the internal coat is abso-solutely necessary for the safe application of a ligature. A thread applied around the carotid artery of a dog so loose as not to interfere with the passage of the blood, is sufficient to cause inflammation, which will block it up completely, as was proved by an experiment made by my able master, the younger CLINE, and which I myself have repeated with the like result.

(3) In the Museum of St. Thomas's Hospital there are two preparations, in which the femoral artery was tied with a broad tape and removed after some hours by the elder **Cline** (*a*), in cases of popliteal aneurysm. In one case, the artery being laid bare, a double tape, about an inch broad, and one piece lying over the other, was passed by means of an instrument behind the artery. The piece of tin which conducted the tape was cut off, and a cork nearly an inch long was laid upon the artery and confined to its situation by means of the upper tape, producing in this way, a sufficient pressure upon the vessel included between the ligature and cork to stop the circulation, and, consequently, the pulsation of the tumour in the ham. The other portion of tape was left loose. The intention of securing the artery in this way was, to compress the sides of the vessel together, and produce union without ulceration. On the ninth day the tapes were removed, and every thing seemed to be going on very favourably when the patient was attacked by a fever, supposed to have been caught from another patient in the same ward, of which he died on the seventeenth day after the operation. On *examination* of the limb after death, it was found that ulceration had taken place, though the whole extent of the artery included in the tape and sinuses were formed both upwards and downwards in the course of the thigh to some distance. In the other case, similarly treated, the operation was successful, but the patient died three months after, of diseased lungs. Both these preparations are in the Museum at St. Thomas's Hospital.

Crampton (now Sir **Philip**), of Dublin, holding (*b*) that the division of the internal and middle coats is precisely the kind of injury which a diseased artery is least able to bear with impunity; and that, "accordingly, secondary hæmorrhage, or even aneurism, is not an unfrequent consequence of this operation," (p. 358,) adopted a modification of **Cline**'s use of a temporary ligature. "The femoral artery was laid bare, at the usual place, by an incision not exceeding three inches in length, and a tape one-eighth of an inch in breadth, was passed under it by means of an aneurism-needle. The ends of the ligature were passed through the holes in the foot of the *presse-artère*, and then crossed through the hole in its stalk. The artery was gently compressed by drawing the two ends of the ligature in an opposite direction, until the pulsation had ceased. The ligature was then secured by passing a small peg of wood through the hole in its stalk." Soon after he had excruciating pain in the calf of his leg, and this continuing, at the end of two hours **Crampton** "determined to relax the ligature, as well to ascertain how far the pain was excited by its pressure, as to observe what progress had been made in the process of coagulation; the peg was withdrawn from the hole in the stalk of the instrument, and the ligature was thus left at liberty to yield to any impulse that it might receive from the artery. I watched for five minutes, with my hand upon the tumour, and as the pulsation did not recur, the peg was replaced, so as to secure the ligature at the degree of tension it now possessed." After forty-four hours, the ligature was completely relaxed; there was no pulsation in the ham; and on the following day it was removed, and the patient cured. (p. 365–68.) **Dease**, of Dublin, also performed the same operation, and loosened the ligature five hours after; but a minute after, "a deep and obscure pulsation was discerned in the tumour, which became more distinct every moment. The ligature was immediately tightened and the pulsation ceased. Nineteen hours after, "the ligature was again completely loosened: we waited with great anxiety for nearly an hour, but the pulsation returned no more." (p. 369.) The patient recovered. **Crampton**'s instrument consists of a short cylinder, having a foot at bottom pierced on either side with a hole for the tape, which having been passed round the artery, has its ends brought up through these holes and then passed through a transverse hole near the top of the cylinder, where they are crossed and tied; a little screw works down upon this tie, by which the ligature can be tightened.

Lisfranc (*c*) says:—"If an artery be of a yellow colour, it is diseased; its sheath must not then be opened, but must be tied with the vessel; he has often seen **Dupuytren** follow this excellent practice with success." (p. 282.)

He prefers opening the sheath with his nail, rather than by raising it with forceps and cutting it with a knife, or opening it with a director." (p. 282.)]

(4) The application of two ligatures, and the division of the artery between them, as recommended by **Abernethy**, is now very rarely adopted, and a single ligature is certainly preferable; yet I cannot think with **Abernethy**, that his operation is advisable as safest, when the experience of the Surgeon who operates is not large. "Though

(*c*) Clinique Chirurgicale, vol. i.

an experienced and skilful operator," says he, "may accomplish this object with very little disturbance of the artery, from its natural situation and connections; yet I cannot but suspect that Surgeons in general may not be so successful, especially in cases where, from the deep situation of the vessel, the surrounding it with a ligature depends more on feeling than on sight." (p. 248.)

It does not appear whether Abernethy originally proposed the division of the artery between the ligatures, to admit the retraction of its ends, or whether he was aware of Galen's advice (*a*) on this point, which was to the same effect. "If the artery be large," says Galen, "and if it can be cicatrized beyond the aneurysm, the whole of it should be cut through, and oftentimes that very practice prevents the danger from hæmorrhage; for it appears plainly that when a complete transverse division is made, both portions of the artery retract on either side, the one above the part and the other below it."

1425. After the performance of the operation for aneurysm, the limb is to be put into such position, that the artery be not stretched; the patient should be kept in the most perfect bodily and mental quiet, should be surrounded with well-advised assistants, and treated according as inflammatory or spasmodic symptoms occur. After the operation of opening the sac, the dressing is to be renewed every third or fourth day; when the ligatures separate, and the wound is filled with granulations, its edges are to be brought together with sticking plaster. After the Hunterian operation, the wound is to be treated as one which is to be cured by quick union. In these modes of treatment, immediately after the artery is tied, the pulsation in the aneurysmal sac ceases, the swelling gradually becomes smaller, and at last completely disappears. The pulsation, however, shows itself anew, and often very quickly, in consequence of which, the Surgeon may fall into error, if he suppose that it results from relaxation of the ligature. The pulsation is rather a proof that the ligature is well applied, and that the blood again passes into the aneurysmal sac by the collateral branches. It is of uncertain duration, and there is generally no fear of enlargement of the sac, which slowly lessens. It must, however, be remembered, after Hunter's operation, in aneurysm at the bend of the arm, upon the back and palm of the hand, and foot, that in consequence of the numerous anastomoses the blood can again distend the aneurysmal sac (*b*). The pulsation which recurs in an aneurysmal sac, after Hunter's operation, depends either on the flowing of the blood into that part of the artery between the seat of ligature and the sac, or on the collateral branches which open into the sac, or on the regurgitation of the blood into the sac from the artery below it (1).

Wedemeier (*c*) has communicated a case, in which, after tying the femoral artery for popliteal aneurysm, the sac burst in the ham, and bleeding ensued, which rendered amputation necessary.

[(1) Guthrie mentions, that "it is not uncommon for a pulsation to be felt in the tumour a few hours, or in a day or two after the operation from this very cause, (the large size and direct communication of the collateral branches with the artery below the ligature,) but it very rarely continues." (p. 153.) I do not think this so common as just stated, for I do not recollect to have noticed it above two or three times. But I do not think that the absence of perceptible pulsation is a positive proof that no blood gets into the aneurysmal sac after the artery has been tied, as most probably it does for a time; and the distinctness of the pulsation depends merely on the quantity which flows into the sac.

In a case of popliteal aneurysm, for which I tied the femoral artery on Sept. 12, 1840, pulsation was thought to be felt in the sac twenty-four hours after the operation, but I could not satisfy myself that it really existed till the third day. After this, it continued to pulsate feebly, but distinctly, for about two months, when its pulsation again in-

(*b*) Scarpa, above cited.—Wedemeier; in Langenbeck's neuer Bibl. für Chir. u. Ophthalm., vol. ii. p. 560.

(*c*) Rust's Magazin für die gesammte Heilk., vol. vi. p. 220.

creased a little; and under this condition he left the house at the latter end of December. But the most remarkable instance with which I am acquainted was a case of carotid aneurysm as large as a walnut, for which my friend **Green** tied the right carotid artery in April, 1831. The pulsation did not immediately cease on the application of the ligature, but it did in the course of the following hour; on the following day, however, it recurred feebly, and continued, though diminishing, till the seventeenth day, but it never ceased. The ligature came away on the thirty-fourth day, and on the forty-seventh the pulsation was again distinct, though feeble. In the course of the following fortnight the sac increased in size, and the pulsation increased correspondently with it. **Green** thought the aneurysm was situated at the bifurcation of the carotid, and that the pulsation was kept up by regurgitation from the internal carotid. It was a curious circumstance, in reference to this case, that the jugular vein of the same side, on the day following the operation, began to pulsate, and continued to do so frequently though not constantly. The patient had also an aneurysm in the other carotid. Perhaps the preparation in the College Museum of an aneurysm of the carotid artery just before its division, and nearly filled with clot except at the upper part, towards which the current of blood has been directed, may correspond with **Green's** case.—J. F. S.]

1426. Two circumstances are specially to be dreaded after the operation for aneurysm, to wit, *Bleeding* and *Mortification* of the limb.

1427. *Bleeding* is the more to be dreaded; the larger the arterial trunk which has been tied, the nearer the ligature lies to a large collateral branch, or if the tied artery be in a state of chronic inflammation, or otherwise changed by disease. The bleeding generally occurs between the fourth and fifth days, but in many cases later. As soon as it takes place, the artery must be compressed above and below the bleeding part, and if the bleeding be not thereby stopped, the wound must be carefully examined, and the artery taken up afresh. After the operation by opening of the sac, the bleeding may take place from the upper or lower end of the artery, or from collateral branches opening into the sac.

[In **Hunter's** first case (*a*), " on the ninth day after the operation there was a considerable discharge of blood from the part where the ligatures passed out," (p. 150,) but it was stopped by pressure with a tourniquet, and did not recur. In his second case, in which the wound was made to unite by granulation instead of quick union, " on the nineteenth day there was an hæmorrhage from behind the muscle, the swelling of which rendered it nearly as difficult to come at the vessel as if the parts had healed by the first intention; the bleeding was stopped by applying pressure, after having lost about 10 or 12 ounces. On the twentieth there was a slight bleeding which was readily stopped, yet five hours afterwards the femoral artery gave way, and he lost about one pound of blood before the tourniquet was applied. The artery was laid bare and tied a little higher up, the patient being very weak and low; in this state he continued till the twenty-third day without bleeding, when it bled again from a small vessel. On the twenty-sixth a considerable hæmorrhage having taken place, he became faint, then delirious, had vomiting with hiccough, and died the same day." (pp. 159, 60.) No bleeding occurred in **Hunter's** other three cases.

One of the most interesting and anxious cases of after-bleeding happened under my colleague **Green's** care in 1825, in a case of axillary aneurysm, for which he tied the subclavian artery external to the scalene muscles, on the 2nd of August of that year. Nothing peculiar occurred at the operation. He suffered a good deal from constitutional excitement, which, however, subsided. On the afternoon of the 14th there was a sudden bleeding in a jet of five or six inches, and he lost very quickly, it was believed, more than a pint of blood; it ceased, however, by firm pressure with a wadding of tow kept up for 10 or 15 minutes, after which all the dressings were removed and linen dipped in cold water, and replaced every 10 minutes, was laid over the wound. On the following day pulsation in the wound was observed, but it almost entirely ceased two days after, and on the 26th the wound was healed, all but the middle. The ligature came away on the 29th, that is, 27 days after the operation. Oct. 31. A small sinus still continues open, from which there has been a slight discharge. About midnight, while he slept, a gush of blood occurred from the wound, which was readily stopped by pressure. It was attended with very great pain in his

---

(*a*) Trans. Med. and Chir., vol. i. above quoted.

arm. On the following evening bleeding recurred as he was making water; the blood, which was arterial, rose in a jet five or six inches, and was in as large a stream as the wound would permit; it was easily stopped by pressure for an hour and then cold wet rag applied. There was no further recurrence of bleeding, and he recovered. On the 12th of December pulsation was felt in the radial artery. After this time nothing of importance occurred, and he got well.

From this case and from two or three others I have seen, I think it must be inferred that when bleeding occurs at the wound after the application of a ligature, it is advisable to do as little as possible, unless the bleeding be so great that the patient's life is in immediate danger. Even the continuance of pressure after the blood ceases to flow had better be left alone, as I have already mentioned, in the treatment of some wounded arteries. The strictest quietude, and the application of cold evaporating washes, should be trusted to, and will be oftentimes successful. But the application of a ligature higher up must be always undertaken with great fear of the result, as generally the cause of want of union at the first placed ligature being a diseased state of the artery, it may be justly dreaded that the vessel may be similarly affected still higher up, and that the same consequences will ensue when the ligature begins to separate. I am inclined to think that if the bleeding be so severe as not to admit delay, I should amputate the limb, not that the actual state of the artery would be other than if it were simply tied; but there would be the advantage, if bleeding recurred, of having the opportunity to apply the actual cautery more efficiently than could be otherwise done; and as this practice is very successful, when, after amputation under ordinary circumstances, the sealing up of the artery has not happened, and either without or with its extremity assuming an aneurysmal character, repeated after-bleedings occur, so I think the actual cautery might be applied successfully to a diseased artery in aneurysm.—J. F. S.

In connexion with this subject may be here mentioned the occasional, though rare recurrence of aneurysm, in a sac which had disappeared after tying the artery above it. Two instances of this kind are mentioned by GUTHRIE (a). The first a popliteal aneurysm, for which the femoral artery was tied by GUNNING, of St. George's Hospital, on *27th April*, 1821, and the patient dismissed cured on the *30th June* following. On the *20th July*, 1825, he was readmitted under JEFFREYS, stating that the swelling had entirely disappeared soon after he left the hospital in 1821; but that six weeks since he had noticed its return, of the size of a hen's egg, in the upper part of the ham. "The tumour (on his return) occupied the lower third of the thigh, filling up the whole of the popliteal space, and projecting considerably on each side of the limb, between the hamstrings and the exterior muscles situated on the forepart of the thigh. It appeared to consist of three lobes, and was altogether as big as an ostrich egg. The pulsation in it was feeble but distinct, the skin covering it of its natural colour, and he did not complain of much pain." (p. 155.) He would not submit to having the artery tied, but determined on amputation, which, however, was deferred in consequence of violent salivation from taking a scruple of rhubarb and five grains of calomel, till *5th September*, when the limb was removed "between the tumour and the part where the femoral artery had been tied. A large vessel, which appeared to be the femoral artery, and eight smaller ones, were tied;" but he became faint and sick during the dressing of the stump, and eight hours after died. On *examination*, "the femoral artery was found to be obliterated, for the space of half an inch, at the part where the ligature had been applied four years ago, and immediately below it two small branches were observed to enter the continued trunk of that vessel, These branches were equal to half the diameter of the femoral artery. The anastomosing branches, given off above the obliterated portion, were a good deal enlarged." (pp. 155, 56.) The second case was also a popliteal aneurysm, for which the femoral artery was tied by BRIGGS, *6th March*, 1829. "The pulsation in the tumour ceased, and it diminished very much in size. It was only in *June* he was able to go to work, when the swelling had entirely disappeared. In *September* it began to appear again with pulsation, both the swelling and pulsation being soon greater than before." Compression of the leg and swelling was employed, but could not be borne. "A hard compress, in fact a narrow roller four inches in length, was applied on the inside of the thigh, just above the knee and above the inner hamstring muscles, which was firmly retained in that situation night and day. This gave him relief by taking away the pain, which was principally felt in the toes and ankle. This compress he wore for two months, at the end of which time the pulsation had ceased, although the swelling had not entirely subsided." (p. 159.) A year after there was no appearance of a swelling.]

1428. *Mortification of the Limb*, after tying the principal trunk of an artery, depends on the impossibility of properly sustaining the circulation in the limb by the collateral branches, and by the anastomoses of the capillary-vascular system. Perhaps such unyielding condition of the collateral vessels as does not admit properly the restoration of the circulation, is also a principal cause of secondary hæmorrhage, inasmuch as the blood is driven with so much more force against the seat of the ligature, and thereby tearing of the artery is easily produced. The circulation is most easily restored in young subjects, and with a certain energy of circulation. After tying the principal artery of a limb, if it be even ultimately well nourished, the limb is always more or less numb, insensible, and has its natural warmth diminished. In proportion as these symptoms are slighter, there is greater hope that the circulation will soon be restored. It is endeavoured to promote the circulation with warm flannel, or warm bags filled with sand or aromatic herbs so applied that the limb is not at all pressed, and renewed as often as they begin to cool. Subsequently warm applications of spirituous or aromatic fluids are to be used. After some days usually sensation and warmth recur, the latter often to a high degree, and continues, although the limb be not enveloped in warm bags or overlays. It is not uncommon that, although subsequently the circulation recur properly, the extreme parts of the limb, to wit, several of the toes, mortify. If, after persisting for several days in the use of the above-mentioned remedies, and of careful rubbing, the sensation and warmth do not return, there is the greatest danger of the limb mortifying. It then swells considerably, becomes bluish, and if the patient do not die in consequence, amputation is the only remaining remedy, but it rarely has a favourable issue.

(a) Cited at head of Article.

[Sometimes, although the operation go on favourably, and the ligature-wound heal, yet the aneurysmal sac will burst and discharge its contents; this happened in JOHN HUNTER's third operation (*a*), four weeks after the operation, "but it healed up like any other sore, and at the end of three months he was perfectly recovered." (p. 161.)]

1429. As regards the preference of the old, or of the HUNTERIAN operation, it may be assumed generally of the former—*first*, that on account of the usually deep situation of the artery, and of the nerves and veins connected with it, which parts have changed their natural place, it is always extremely complicated, difficult, and excites considerable injury, especially as the sac is generally in the neighbourhood of a joint; *second*, that if the aneurysm be consequent on an inflammatory, ulcerative, or otherwise diseased condition of the artery, the ligature, although applied both above and below the sac, may be placed on some part of the artery where the walls are not disposed to adhesive inflammation; *third*, that in this operation there is always a considerable quantity of blood lost; *fourth*, that on account of the large and deep wound in the neighbourhood of the joint, *anchylosis* commonly remains, and, *fifth*, that after-bleeding is frequent after opening the sac. On the other hand, by this operation all the coagulated blood is removed from the sac, which, after the HUNTERIAN operation, if not absorbed, in rare cases produces inflammation, suppuration, and bursting of the sac.

1430. The advantages of HUNTER's mode of operation are in general much greater than those of the old; for therein the place for applying the ligature may be selected, and probably upon a part of the artery which is best suited for adhesive inflammation; the operation itself is accom-

---

(*a*) HOME's account, above cited; in Trans. Med. and Chir., vol. i.

panied with much less difficulty and pain; after-bleeding is more rare; the patient can use his limb as well after as previous to the operation; experience speaks in favour of HUNTER's mode of operation. Finally, in many cases where, on account of the seat of the aneurysm being near the trunk, the opening of the sac is not possible, this operation is alone admissible

1431. Important, however, as is the superiority of HUNTER's over the old operation, so that by many Surgeons it is considered unconditionally as the best mode of operating, yet after what has been already said about the accidents after the operation, the opening of the sac must be conceded if the aneurysm be diffused, and accompanied with much extravasation of blood, and in aneurysm at the bend of the arm (1), on the back and front of the hand and foot. (*par.* 1425.)

(1) SCARPA, WALTHER, and others, consider two ligatures in circumscribed aneurysm at the bend of the arm, as a superfluous proceeding. Compare, on the contrary, the cases given by WEDEMEIER (*a*).

The opening of the sac has also been considered preferable to HUNTER's operation, in those cases in which the aneurysmal sac is very large, and its absorption not to be expected; experience, however, shows that even the largest sacs will gradually diminish.

1432. The proposal of *torsion* of the artery in its continuity by means of a DESCHAMPS' needle (1), AMUSSAT's (2) division and thrusting back of the internal coats of the artery, (*réfoulement de la membrane interne, et moyenne de l'artère,*) and TAVIGNOT's subcutaneous tying of the superficial arteries, must be here noticed.

(1) THIERRY (*b*) and, subsequently, LIEBER have proposed torsion or twisting the arterial tube, instead of tying it, for the cure of aneurysm; and this mode of obliterating the vessel has been practised by them on a living animal. The artery having been exposed, a DESCHAMP's needle is passed beneath so as to raise it, and then, by means of a stick, a twisting is produced, (without, however, opening the vessel,) proportioning the number of turns to the size of the artery; the wound is then closed, and having nothing extraneous in it, the obliteration is as complete as if it were tied with a ligature. BÉRARD (*c*) properly objects to this practice, that if the artery be healthy, there is no fear of the ligature causing bleeding by prematurely cutting through it; but if the artery be unhealthy and friable, the twisting will at once cause tearing of its coats.

(2) The thrusting back of the arterial coats with forceps was the result of experiments performed by CARON DU VILLARS, and repeated by AMUSSAT.

In AMUSSAT's *division and thrusting back the internal coats* (*d*), the artery is laid bare by a pretty large cut, as in the ordinary mode of operation, and isolated for some lines. The artery is then seized transversely by the right hand with a pair of torsion forceps, the branches of which, when closed, touch very exactly, so that the vessel lies directly between its branches; a second pair of forceps is then applied with the left hand on the opposite side, at the distance of some lines, also transversely. The vessel is so held with the two pairs of forceps, that the forceps can be laid parallel, and not at an acute angle, and then pretty strongly pressed together. By these means the inner and middle coats of the artery are torn, and only, in the interspace between the two pairs of forceps, remains a ring consisting of all three coats of the artery. The thrusting back of the internal coats is next effected solely by the forceps farthest from the heart, because this, according to AMUSSAT's experience, is sufficient; and the

thrusting back of the coats upwards towards the heart is difficult of performance and insufficient. The forceps destined for the thrusting back are supported sometimes by the point, sometimes by the opposite end, on the fixed forceps, and so acting alternately and like a lever, they thrust back the internal coats, first on the one, then on the other side, by which all tearing of the artery is prevented. When the operation is thus completed, the wound is to be closed, and the cure attempted by quick union. Amussat has published numerous experiments on brutes, and the operation also on man, with successful result.

According to Tavignot's plan (*a*), the two ends, laid together, of a silk thread are to be passed through the eye of one small and one large curved needle, and the loop allowed to hang loosely. The smaller needle is to be carried over the artery, the larger one is to take a directly opposite direction to it, is to pass through the hole made by the former, away under the artery, and carried out again at the same hole. From the opening of each needle-track the loop of one and the two ends of the other thread hang down; the one is then pushed through the other; another coloured thin silk thread is passed through each of the loops (so that the loops may, when needful, be again loosened); the two ends are then pulled, by which the loops are drawn together. The ends are fastened to a horseshoe-like instrument.

On examination of arteries which have been subjected to this operation, the following changes are found. At the part where the forceps next the heart was applied the external coat only remained entire; then followed a ring about a line broad, consisting of all the coats of the artery; beneath this again, the internal coats were divided, and thrust back under the cellular coat, to the extent of two or more lines. At this part which externally felt hard, the area of the artery was considerably diminished by the thrust back and inverted coats, and subsequently still more so by the ensuing swelling and effusion, whereby the complete obliteration was effected.

The various remedies which have been proposed for the treatment of aneurysm, or which have been made use of, are still to be mentioned in historical review.

1. *Cutting into and plugging the aneurysm.* 2. *Suture of arterial wounds*, with a needle and thread wound round it. Lambert effected obliteration of the artery by this practice in man, and Amussat in brutes. 3. *Application of a ligature with a running knot*, for the purpose of *gradually* compressing the vessel. (Dubois, Larrey.) 4. *Acupuncture;* E. Home (*b*) thrust a needle into an iliac aneurysm, heated it with the flame of a spirit lamp, and allowed it to remain twenty or thirty minutes. The soft and, notwithstanding its previous tying, still pulsatory swelling, gradually became harder, lost its pulsation, and the needle exhibited hardened clot every time it was drawn out. Velpeau (*c*) proposes the introduction of a needle into the artery when laid bare, in which it is to remain for at least four days. One needle is sufficient for an artery as large as a feather; two or three are necessary for larger arteries. The same result is effected by means of a thread carried round the artery, and tied on a little pad. According to Phillips (*d*), the thrusting in of several needles into the aneurysmal sac, or the introduction of a silver thread; in sixty hours inflammation ensued, after which the sac shrunk as in Hunter's operation. Pravaz has proposed to use galvanism, with needles thrust into the sac, in order to excite more quickly the coagulation of the blood. Leroy d'Etiolles (*e*) applied the extremities of two compressors, at the distance of some inches from each other, for the purpose of coagulating the blood in the interspace between them; he also applied ice on the part, and used acupuncture and galvanism. 5. *Cauterization* with moxas (Larrey). 6. The *introduction of mechanical plugs* of wax and so on into the arteries, and the compression of the ends of the artery or ligatures. 7. The *introduction of threads* into the artery (Jameson, Worms, Amussat.) 8. Various modes of *compressing the artery* between the rounded branches of forceps, and tying it below this part, according to Amussat's experiments on brutes.

1433. In aneurysms in which tying the artery between the swelling and the heart is impossible, Desault (*a*) and Brasdor have proposed laying bare that side of the swelling farthest from the heart and tying it, for the purpose of effecting obliteration of the artery up to the nearest collateral branches, by the stagnation of the blood in the aneurysmal sac. Deschamps (*b*) followed out this proposal with unsatisfactory result; so also Astley Cooper (*c*). From these cases it has been improperly determined to reject this practice unconditionally (*d*), as it can only answer our expectations *if no branches arise from the artery between the seat of ligature and the sac, or from the sac itself* (*e*). This opinion is confirmed by the observations of Wardrop (*f*), Lambert (*g*), Evans (*h*), Bushe (*i*) Mott (*k*), and Montgomery (*l*), who, in aneurysm of the carotid artery, have tied the vessel above the swelling, and effected a cure.

Dupuytren supposes that the small branches between the sac and the seat of ligature may become useful, as they proportionally afford a passage for the blood, and prevent the too great extension and tearing of the sac. Wardrop also considers the objection of some branches between the sac and the ligature as no necessary reason against the operation.

[The operation of tying the artery beyond the aneurysmal sac, was according to Boyer proposed nearly sixty years since by Brasdor in his lectures, but never performed by him; it was also recommended by Desault, as feasible where it was not possible to tie the vessel between the heart and the sac, but neither did he perform it. The operation, however, was at last undertaken by Deschamps, in a man of sixty years old, who had a femoral aneurysm, seventeen inches in circumference, so high up that there was not a finger's breadth between the sac and Poupart's ligament. The vessel was tied below the sac in hope that the blood, arrested in its progress through the vessel, would coagulate. The tumour, however, continued to pulsate and increased so much after the operation that on the fourth day, its bursting being dreaded, Deschamps, compression of the iliac artery being made as it left the belly, "plunged the bistoury into the upper part of the tumour and opened it down to the bottom." * * * A large quantity of fluid blood immediately escaped and he removed a mass of clot and fibrinous concretions larger than the fist. The sac having collapsed, a long space was left between the upper angle of the cut and the compressing pad. He therefore continued the cut upwards as far as the hand of the assistant who was making pressure, so that he might discover the precise situation of the gap in the artery, which he could only see occasionally, being constantly flooded with the blood, notwithstanding the care taken to compress the artery. A long probe was passed into the upper portion of the vessel, which was raised up as high as possible, and the ligature quickly applied, on account of the enormous loss of blood. * * * As blood was seen to flow from below upwards he applied a ligature of wax thread tied with a double knot below the sac. * * * The patient lost such a quantity of blood that he fell into a state of syncope, from which he did not recover; * * * he gradually sunk and died eight hours after the operation." (p. 196–98.) Both operations were performed in a very bungling and inefficient manner; for, as appeared by Deschamps' dissection, in the first, "the ligature included the artery, the femoral vein and a small portion of the great

(*l*) Medic.-Chir. Review, 1830, Jan. In this case the sac enlarged ten weeks after the operation, formed an abscess, on opening which eight ounces of stinking chocolate-like fluid escaped. The opening was enlarged, all the blood clot removed, the sac filled with charpie, and permanent cure effected.—Oppenheim, N. W., Ueber die Unterbindung der grösseren aneurysmatischen Gefäss Stämme an den, vom Herzen entfernten, Theile der Geschwulst; in Rust's Magazin, vol. xxx. p. 100.—Marjolin et Berard, Dictionnaire de Médecine, vol. iii. p. 60.—Vilardero, Thèse de Paris, 1831, No. 158

adductor muscle; and in the second, the upper ligature was situated three lines above the aneurysmal sac, and included the femoral artery and a third of the *profunda* which had been pierced by the needle; the ligature of reserve placed above the last, passed between the femoral artery and the *profunda* accurately surrounding the former, the lower ligature applied in the second operation was upon the artery six lines below the sac, and the vein had been wounded by he needle." (p. 199.) From this account it is pretty clear that the higher origin than usual of the *profunda* and its firm connexion with the aneurysmal sac, would have little to do with the fatal result of this horrible operation, the ill success of which, alone to be expected, could not however present any real objection to the operation proposed by Brasdor, if properly performed.

Astley Cooper tied the femoral artery below the sac of an external iliac aneurysm "between the origins of the epigastric artery and of the *profunda.* The pulsation continued, but the tumour did not increase in size after the operation. The ligatures separated favourably. The aneurism diminished so considerably, that it was conceived in a little time, if its diminution continued, it would be possible to tie the external iliac artery above the tumour. The patient went into the country to recruit his general health, where the aneurism burst underneath the *peritonæum,* and he died in consequence of extravasation of blood into the cellular membrane of the *pelvis* and *scrotum.* In this instance, the femoral artery was tied below the origin of the epigastric and circumflex iliac arteries; a current, therefore, continued to pass through the sac into these vessels; consequently the blood was not at rest in the aneurism, and did not coagulate. After the ligature of the artery, the blood was transmitted more readily through the internal iliac than through the arteries which originate below the aneurism, namely, the epigastric and circumflex iliac. The contraction of the sac, therefore, appears to have been the consequence of the diminution of the stream which passed through it, in the same manner as an aneurism contracts, although a current enters it after the ligature of the artery, at a distance from the disease." (pp. 301, 302.)

For some time this operation was entirely given up, and was, perhaps hastily, designated by Allan Burns (*a*) as being "absurd in theory, and experience proves that it is ruinous in practice." (p. 159.) Wardrop (*b*), however, revived it in 1822, considering "that the changes which such an operation produces both in the artery and sac, are precisely those which nature employs when she cures the disease by a spontaneous process." (p. 19.) In the course of his reasoning to prove the superiority of tying the artery beyond the sac, over tying it between the heart and the sac, he makes some very odd and, as seems to me, incorrect observations; for instance, "when the artery is tied on the cardiac side, the blood cannot make its escape, and cannot be pushed through the capillaries into the veins. It must remain in the sac, and must either be absorbed or be evacuated by a process of inflammation and ulceration of the sac." (p. 22.) Now, unless the disease be of long standing, and of such size, that whatever practice be pursued, burst the sac will, it is rare that the bulk of the contents of the sac are absorbed; the greater quantity of the blood is generally fluid, and the rapid subsidence of the swelling, after the artery has been tied above, proves clearly that the blood does make its way into the veins without any "pushing," whilst the remaining coagulated part quietly rests, often for years, without causing any inconvenience, as will be shown by the dissection of Astley Cooper's and Key's cases, hereafter to be mentioned. Inflammation and ulceration of the sac are of rare occurrence, so far as I have had opportunity of observing. Wardrop's explanation of the diminution of the bulk of the aneurysmal tumour, after tying the distal part of the artery, is one utterly incomprehensible. "The fluid blood," says he, "can find a *ready exit into the trunk* from whence it came, and thus again passes into the circulation, in place of, as in the other case, having to passs through the capillaries into the veins; and, as nature immediately finds a new channel, there is no more blood impelled into the tumour afterwards." (p. 22.) How "the fluid blood can find a ready exit into the trunk from whence it came," is rather puzzling I should think to the blood, which must be constantly "pushed" forward by every fresh portion propelled by the heart; and it must be a very "new channel" indeed which nature finds, if the blood have "a ready exit into the trunk from whence it came." No Surgeon who has observed the consequence of a ligature applied between the heart and the aneurysmal sac, presumes to say that "to allow the process of coagulation to go on in an aneurism, it is necessary to put a complete stop to the circulation of the blood in the tumour." (p. 60). Home (*c*), in describing Hunter's operation, speaks only of "the force of the circulation being taken

---

(*a*) Surgical Anatomy of the Head and Neck.

(*b*) Case of Carotid Aneurism successfully treated by tying the artery beyond the tumor; in Med.-Chir. Trans., vol. xiii. 1825; also On Aneurism, and its Cure by a new operation. London, 1828, 8vo.; from which here quoted.

(*c*) Trans. Med. and Chir., vol. i.

off from the aneurismal sac." (p. 147.) In some of **Hunter**'s cases the pulsation did continue; and it is probable that there is always some degree of circulation through the aneurysmal swelling, after the ligature has been applied, although not sufficient to convey an impulse to the walls of the sac, which is only produced when the disease has existed so long that the anastomosing vessels have begun to enlarge and bear a share in the circulation, as they do in spontaneous cure of aneurysm. It is not also "a curious circumstance that the natural or spontaneous process does not affect a cure, on the principle of the Hunterian operation, by *completely arresting* the passage of the blood into the sac;" for, as just noticed, **Hunter**'s operation proposes nothing of the kind. Nor is the "natural or spontaneous process in strict conformity with the principle of the operation I (**Wardrop**) am now endeavouring to establish; that is, by the formation of *a barrier in the artery beyond or at* the distal side of the aneurism." Nor is it correct to state that "in a case of aneurism Mr. **Mackelcan** found that nature had nearly completed a cure of the disease on this principle;" for "the carotid artery was plugged up, and the large aneurismal swelling was filled with a coagulum, leaving only a comparatively small channel for the blood to pass into the subclavian artery;" (p. 61) which was certainly *not a barrier* in the artery beyond, or at the distal side of the aneurysm. The operation of tying the artery beyond the sac may be permissible in some instances when its ligature on the hither side cannot be performed, but the principle on which it must be conducted, and the success which may be therefrom expected, must be otherwise explained than as **Wardrop** has set it forth.—J. F. S.

With regard to the operation of applying a ligature beyond the aneurysmal sac, **Lawrence** (*a*) observes "the circumstances under which aneurisms are placed, in reference to the trunk, and with respect to such an operation are not always alike; in fact, we may distinguish two cases in which the results of this operation may be very different. In the first place, we might reasonably expect to succeed if we could place a ligature upon an artery leading from an aneurismal tumour. under circumstances that would prevent the current of blood through the aneurism. We should expect here the same result as when we cut off the supply of blood, by placing a ligature between the aneurismal tumour and the heart; but there are very few arteries that are so circumstanced, perhaps the carotid artery is the only one. If an aneurism be situated at the lower part of the carotid artery, suppose the common carotid artery be then tied, we know that no branch is given off between the ligature and the aneurism, by means of which the circulation in the tumour can be carried on; therefore, if it were tied effectually, there could be no current of blood through the tumour, that the coagulation might take place necessary for the cure of the aneurism. Mr. **Wardrop** first tried the operation in a case of this kind, and it was completely successful. The operation was subsequently performed in a case of aneurism of the carotid artery, and it appeared again to have been completely successful, so far as the contraction of the tumour was concerned; but the patient unfortunately died in consequence of hæmorrhage from the upper orifice of the artery where it had been tied, from the remote orifice of the artery, a circumstance, however, that does not at all diminish the value of the inference that is to be drawn from the operation, as far as regards the principles upon which it is founded. When, however, we come to aneurism on the trunk of the axillary, or femoral artery, the case is different; if we tie the vessel *beyond* the tumour, in either case there are important branches given off between the disease and the ligature, by which, probably, a current of blood will continually be kept up through the tumour. In a case of aneurism of the femoral artery, for instance, we should hardly be able to tie the trunk of the vessel beyond the tumour, above the origin of the *profunda;* if, therefore, the *profunda* be left going off either from the aneurismal sac, or from any part between the aneurism and where the trunk of the artery has been tied, we should expect from the active circulation which would be kept up through the tumour, that the operation would fail. In cases of aneurism of the axillary artery, there are a variety of large branches situated, near to the tumour, so that we could not apply a ligature on the distal side, between them and the tumour itself, and these branches would keep up the circulation of the blood through the tumour in the same way that it would be maintained if no ligature were applied. The two cases seem, therefore, to be very different in point of principle; that in which the aneurism is situated near the trunk, and where the vessel gives off no branches between the disease and the ligature; and that in which it is so situated, that numerous branches are given off between where we can apply a ligature, and the situation of the aneurismal tumour. Still, as I have already said, the question is one of experience, and, until it has been fairly tried, we cannot venture to assert that the application of a ligature on the trunks of both femoral and axillary arteries *beyond* the aneurismal tumour, may not be effectual." (p. 165.)]

(*a*) Lectures in Lancet, vol. ii. 1830.

SECOND SECTION.—OF ANEURYSM IN PARTICULAR.

I.—OF ANEURYSM OF THE CAROTID ARTERY AND ITS BRANCHES.

1434. Aneurysm of the carotid artery is usually situated at its bifurcation; it has, however, been noticed on various parts of its common trunk, near its origin, and on its branches, the ophthalmic, temporal, and others. The *diagnosis* rests on the general symptoms which characterize aneurysm; with which it is also to be remarked that the aneurysm does not move in swallowing, like pulsating swellings of other kinds, in the neck, which, for the most part, are connected with the thyroid gland. Besides, it is generally accompanied with violent tearing pain in the entire half of the head, beating in the head, sudden loss of recollection, and, according to the different seat and size of the aneurysm, difficulty in breathing.

BURNS (*a*) has often felt an enlargement of the common carotid, and of the root of the internal carotid, after death and twice during life, forming a swelling as large as a filbert nut, which caused no pain. I have noticed such an expansion in a strong young man, upon the bifurcation of the carotid, which arose after violent exertion; excepting a violent beating it was unaccompanied with any inconvenience, and did not increase for several years. **SYME, J.** (*b*), observed a case of aneurysm of the internal carotid artery, which formed a pulsatory swelling in the throat; and, from its situation, resembled an abscess in the tonsil. Tying the carotid artery did not stop the pulsation, and the patient died.

1435. Tying the carotid artery is the only remedy which can be employed in aneurysm of that vessel, if the seat and size of the swelling especially permit.

ACREL (*c*) has restored the artery in an expansion (*Aneurysma verum*) of the trunk of the carotid artery, by gradual and strong compression as the place permitted, after four or five months, to its natural strength.

1436. Numerous observations have proved that, after tying the common trunk of the carotid artery, the brain is sufficiently supplied with blood, and that no disturbance of its functions ensue. Besides the numerous small anastomoses, the carotids of both sides communicate, and the vertebral arteries, by large inosculations in the region of the cellular sinuses, of the cuneiform process of the occipital bone, the *falx*, and the halves of the *cerebellum*, but especially by one peculiar branch from the deep artery. The vertebral arteries at the same time assume the function of collateral branches.

Tying the carotid artery (previously undertaken by **ABERNETHY** (1) and **LYNN** in wounds) was first and afterwards frequently performed for aneurysm by **ASTLEY COOPER** (*d*). **MACGILL** (*e*), in the space of one month, tied both carotid arteries for tumours of both eyes. Several months after the operation, the patient was well and the swellings had subsided. **MUSSEY** (*f*) tied both carotids at an interval of six weeks, on account of inosculating arterial swellings, and the case recovered.

[(1) **ABERNETHY** was not the first person who tied the carotid artery; for **HEBENSTREIT**, in the fifth volume of his translation of **BENJAMIN BELL'S** *System of Surgery*, mentions a case which he had met with, where the external carotid artery was wounded in the extirpation of a schirrous tumour. The profuse hæmorrhage which instantly

(*f*) American Journal of Medic. Sciences, vol. v. p. 316.

ensued would soon have destroyed the patient, if the Surgeon had not immediately recollected himself and tied the trunk of the artery. "The operation was successful, and the patient lived many years after it" (*a*).

Abernethy's operation (*b*) was performed about 1798 or 9, on a man whose neck was gored by a cow. The horn "had passed beneath and torn the internal carotid artery, and all the branches in front of the external carotid artery. The former vessel was not, however, entirely rent asunder, so that the general course of the artery, and its connexion with the *cranium* remained in the usual state." (p. 117.) The vessels did not at first bleed, but soon did, but this was checked by pressure on the common carotid artery, which could not, however, be borne, and the patient's struggles removing the pressure, repeated bleedings ensued. The wound was therefore enlarged, the artery found and tied, but he died thirty hours after the ligature had been applied. (p. 125.)

Fleming (*c*) successfully tied the carotid in 1803, for secondary bleeding, in a sailor who had attempted to commit suicide. The wound had healed so rapidly that on the seventh day the ligature was completely buried in granulation, and required removal by a cautious dissection." (p. 4.)

The common carotid artery was first tied by Astley Cooper (*d*), in November, 1805, for aneurysm of the right carotid; the ligatures were drawn from the wound on the eleventh day, but the woman died on the nineteenth day, having suffered much from difficulty in swallowing. He tied it in another case in June, 1808; the upper ligature came away on the twenty-second, and the lower on the twenty-third day, and this patient recovered. The account of the state of the vessels thirteen years afterwards will be found below.

Travers (*e*) tied the carotid artery in the following year successfully for a case of aneurysm by anastomosis in the orbit, in a woman of thirty-four years of age.

The carotid artery has since been tied frequently with success; and there is one very interesting instance in which Dr. Robertson, of Edinburgh (*f*), operated in a case where an aneurysm had burst into the *œsophagus*, and the space was so little, that the artery was taken up only half an inch above the bifurcation of the *arteria innominata*; the ligature came away on the seventeenth day, and the patient recovered.

Zeis, of Dresden (*g*), tied the carotid artery in an infant of fifteen months for a vascular *nævus* on the left side of the face. After having exposed the edges of the *m. sterno-mastoideus*, a vein, about the thickness of a quill, was found lying across the bottom of the wound; this he tied and divided. There was not any arterial hæmorrhage, but dark venous blood oozed out, which was stopped by the application of kreosote water. On opening the sheath, and exposing the internal jugular vein, another large gush of blood ensued, and was stopped by kreosote water. The vein which had been tied swelled so much as to excite fear of its bursting, and was therefore tied again higher up; after which the artery was tied with a silk thread. The tumour immediately became smaller and paler, shrivelled up, and exhibited in various spots, a greenish yellow colour, like an *ecchymosis* of four or five days standing. On the fourth day the ligature on the vein came away, and on the following night a considerable venous bleeding took place, which recurred six times in the course of the next twenty-four hours, but each time was arrested by the kreosote water. On the evening of the eighth day the ligature came away; the bleeding ceased, and after seventy-two days the wound had healed. Several weeks after the operation, the tumour had increased with the nutrition of the body, and became very large, when the child cried. About a week before the complete healing of the wound, the child was attacked suddenly with convulsions and *hemiplegia* of the right side; these symptoms continued with increasing debility, and on the forty-ninth day after the attack of convulsions, the child died. The vascular *nævus* had for some days disappeared, leaving only a few folds of the skin. No examination was allowed.

Kuhl (*h*), of Leipzig, has tied both carotids with success at an interval of twenty-seven days, for a pulsating aneurysmal tumour of the scalp, consequent on wound on the *occiput*, from which there were repeated bleedings. The application of the ligature was followed by convulsions, other troublesome symptoms, heaviness and throbbing of the head, for which it was necessary to employ venesection, though the case at last did well.]

1437. *Tying the common trunk of the carotid artery* may be performed at three different places, according to the different seat of the aneurysm, viz.:

(*a*) Scarpa, Wishart's Translation, note, p. 409.

(*c*) Medico-Chirurgical Journal, vol. iii. p. 1.

(*d*) Medico-Chirurgical Transact., vol. i. p. 1.

(*e*) Med.-Chir. Trans., vol. i. p. 222.

(*f*) Dublin Journal of Medical Science, &c., vol. xii. p. 335. 1838.

(*g*) Zeitschrift für die gesammte Medicen, vol. iii. part 1.

(*h*) Radius und Clarus, Beit. zur prakt. Heilkunde. Leipz., vol. ii. p. 245.

first, immediately above the collar-bone; *second*, below the part where the *m. omo-hyoideus* crosses the carotid; *third*, above that point. If the seat and extent of the swelling do not permit the ligature below the aneurysm, it must be applied above (*par.* 1433.) The patient is to be placed horizontally upon a couch, the head supported by a pillow, and the diseased side of the neck turned properly towards the light.

1438. In tying the carotid artery *immediately above the collar-bone*, a cut of two inches and more should be made through the skin and *m. platysma myoides*, from the top of the breast-bone along the inner edge of the *m. sterno-cleido-mastoideus.* When the edge of this muscle is laid bare, it must be separated from its cellular connexion with the *m. sterno-hyoideus* and *sterno-thyroideus*, and drawn outwards, whilst the latter two muscles are drawn inwards, with a blunt hook, by an assistant. The *m. sterno-cleido-mastoideus* is now to be relaxed by inclining the head to the affected side. The internal jugular vein appears in the wound, and must be drawn outwards, with the forefinger of the left hand from the artery, the sheath of which is then to be opened with delicate and careful strokes of the scalpel; or, when the vein has been fixed externally by an assistant, the sheath is to be raised with forceps, and carefully cut into; the artery should be carefully isolated with the handle of the knife, and the ligature applied round it with Deschamps' needle.

The operation is always most difficult at this part, on account of the depth of the artery beneath the *m. sterno-cleido-mastoideus*, and because it is entirely covered by the jugular vein.

Zang (*a*) has proposed that an incision, beginning from the top of the cricoid cartilage, should be carried outwards *between the two portions of the m. sterno-cleido-mastoideus*, and terminate at a quarter of an inch from the collar-bone; the skin and *m. platysma myoides*, and the edges of the wound must be kept asunder with the blunt hook, the cellular tissue and *fascia* of the neck divided, and thus the triangular space formed by the sternal and clavicular insertion of the sterno-mastoid muscle reached. The internal cervical *fascia* is then to be cut through, the thyroid gland drawn inwards, the jugular vein and pneumo-gastric nerve outwards, the artery taken hold of by the forceps, gently raised, and a ligature passed with a proper needle close to the part where the artery is covered by the *m. omo-hyoideus.*

According to Dietrich's proposal (*b*), an incision is to be made on the mesial line of the windpipe, from the semilunar notch at the top of the breast-bone, to the cricoid cartilage, from two and a half to three inches in length, through the skin, cellular tissue, *m. platysma myoides*, and external cervical *fascia*, by which the small veins running from above downwards are avoided. The tendinous connexion between the *m. sterno-hyoideus* and *sterno-thyroideus* is then to be divided, the edges of the wound drawn asunder with a blunt hook, and the muscles just mentioned pushed from the windpipe, with the handle of the knife, and carried towards the shoulder. The branches of the inferior thyroideal vein, as well as the thyroid gland, which appears from the middle to the upper end of the wound, must be avoided. The finger is to be introduced into the wound downwards and outwards, after the cellular tissue has been divided with the handle of the knife, and the vessel is felt enclosed in its sheath, which is then to be opened, the artery a little raised, and the ligature introduced.

As upon the left side the carotid artery lies deeper and nearer to the *pleura*, the jugular vein and pneumo-gastric nerve higher, and the thoracic duct close behind the sheath of the artery, the performance of the above mode of treatment the more difficult.

The following method, proposed by Coates (*c*), is more easy and more sure. A cut from two to two and a half inches long, is to be carried upwards from the upper edge of the breast-bone, upon the inner edge of the sterno-mastoid muscle; from the lower end of this incision, a second is to be made parallel to the upper edge of the collar-bone, to the inner edge of the clavicular part of the sterno-mastoid muscle, about

(*a*) Blutige Operationen, vol. i. p. 233.

(*b*) Above cited, p. 162.

(*c*) Medico-Chir. Trans., vol. xi. pt. ii.

an inch and a half long: the cellular tissue, *m. platysma myoides*, and external cervical *fascia*, is to be divided in the two cuts. A director is then to be carefully thrust under the sternal portion of the sterno-mastoid muscle, which should be cut through three lines from the upper edge of the collar-bone, together with the internal cervical *fascia*. The flap is turned somewhat upwards, and held back with a blunt hook. The cellular tissue is then to be divided, and, if there be much fat, it must be removed partly with the scissors, forceps, or bistoury, so that the vessels, with their sheath, behind the collar-bone, and on the outer edge of the *m. sterno-hyoideus*, may be brought into view. These muscles are to be inclined with the handle of the knife towards the wind-pipe, and the sheath, opened with the greatest care, and without any violence, as the delicate walls of the thoracic duct, which lies close behind the sheath, are torn with the slightest violence. The isolation and tying of the artery is effected in the way already described.

1439. If the aneurysm be higher up, the tying of the carotid artery must be effected *below the part at which the m. omo-hyoideus crosses.* A cut is to be made through the skin and *m. platysma-myoides*, in an oblique direction along the inner edge of the *m. sterno-mastoideus*, commencing at the top of the cricoid cartilage, and terminating an inch from the sternal end of the collar-bone. When the edge of the sterno-mastoid muscle is exposed, it must be separated carefully from the sterno-hyoid muscle, and drawn outwards; the omo-hyoid muscle then appears crossing over the vessels of the neck, and the carotid artery, jugular vein, and pneumo-gastric nerve enclosed in their sheath, with the descending branch of the hypoglossal nerve upon it. The omo-hyoid muscle is now to be drawn outwards and upwards, the thyroid gland inwards, and the jugular vein with the fore-finger of the left hand outwards, and there kept (1). The sheath is now to be opened, immediately where it covers the carotid artery, either with a director, or, if carefully raised with the forceps, with the scalpel held flat, or, what is best, with some careful strokes of the scalpel. The artery should now be separated from the surrounding parts with the handle of the knife, to an extent sufficient for passing around it the ligature with DESCHAMPS' needle.

As the swelling up of the jugular vein often renders the isolation of the artery very difficult, this may be facilitated by applying compression on the vein above, with the finger. For the purpose of not injuring the important surrounding parts in isolating and tying the artery, it is to be borne in mind that the jugular vein lies on its outer side, and upon it; the pneumo-gastric nerve between the vein and artery, and the sympathetic nerve behind them. As important varieties in the course of the vessels of the neck, in connexion with this operation, it must be remembered that the division of the carotid artery often takes place deep in the bottom of the neck, and that the vertebral artery arises from the *aorta*, or the subclavian ascends along the side of the carotid, and close behind it. If the artery be laid bare, as proposed, to a great extent, two ligatures must be applied, and the artery tied at the upper and lower part of the exposed portion (*a*).

[(1) ASTLEY COOPER (*b*) observed in his first operation for carotid aneurysm, that "the motion of the internal jugular vein produced the only difficulty in the operation, as, under the different states of breathing, it sometimes presented itself to the knife tense and distended, and then as suddenly collapsed." (p. 3.) This, however, is not always the case, as in an instance mentioned by HODGSON where the carotid artery was tied for a spurious aneurysm, the result of wounding the vessel with a penknife, "the jugular vein afforded no trouble in the operation; it was not even seen." (p. 332.) And in another operation, by Dr. JOHN BROWN, of Meath (*c*), for wounded carotid by a penknife, the vein "did not appear, nor was it a source of the slightest inconvenience in the operation." (p. 305.)

If, however, the vein be wounded in the operation, it must be tied as was done by SIMMONS, of Manchester (*d*).]

1440. If the carotid be tied *above the crossing of the m. omo-hyoideus*, (which is only possible when the aneurysm is seated in the branches of

---

(*a*) HODGSON, above cited, p. 342.

(*b*) Med.-Chir. Trans., vol. i.

(*c*) Dublin Hospital Reports, vol. i.

(*d*) Cycloped. of Pract. Surgery, vol. i. p. 262.

that vessel, or when the aneurysm is deep, and the artery must be tied above it,) the cut must be carried either from the top of the cricoid cartilage two inches upwards, in the direction of the inner edge of the sterno-mastoid muscle, or commenced at the upper edge of the thyroid cartilage, and, on the contrary, carried down a sufficient length along the inner edge of the sterno-mastoid muscle. In this case the operation is to be proceeded with as before, only the omo-hyoid muscle must be drawn downwards. In other cases, when the skin, *m. platysma myoides* and cellular tissue are divided, the edges of the wound must be held asunder, a thin layer of cellular tissue divided; and, in the triangular space formed at the lower end of the wound, by the crossing omo-hyoid muscle, at the upper end of the wound, by the digastric muscle, and externally, by the inner edge of the sterno-mastoid muscle, the artery must be isolated, as already mentioned (*a*).

The superior thyroideal vein above the cricoid cartilage, crosses the common carotid artery, and with it the laryngeal and pharyngeal vein, as well as some branches anastomosing with the external jugular vein, run together before the carotid, and partially form some anastomoses. These veins must be avoided, and drawn upwards (1), and the superior thyroideal artery inwards.

[(1) I have on one or two occasions seen these veins wounded in tying the carotid artery; they bled very freely, but were soon stopped by a little pressure.—J. F. S.]

1441. When in one or other way the ligature has been carried round the carotid artery, it must be fastened sufficiently tight with two single knots; the one end of the ligature cut off near the knot, the other brought out of the wound by the shortest course, and the union of the edges of the wound effected with sticking plaster. Such symptoms may occur after the operation as have been already generally mentioned. The patient should be kept quiet in bed, with his head somewhat raised, and bent forwards. On the fourth or fifth day the dressing is to be renewed. The patient should be treated antiphlogistically, according to the symptoms, and with suitable antispasmodics, if cramps come on. After tying the carotid, it is not uncommon that, on account of the great anastomosis, the pulsation in the sac reappears; no further increase, however, is to be feared; it gradually becomes weaker, and the sac diminishes.

For the history of the ligature of the common trunk of the carotid artery, and the collection of the hitherto known cases, see Dietrich (*b*).

[The following is the account of the dissection of the second case in which Astley Cooper tied the left common carotid artery in 1808, for aneurysm (*c*), the patient having died thirteen years after of apoplexy (*d*). "The disease of which he died sufficiently attested the freedom of the circulation, as well as its force in the cerebral vessels, on the side on which the carotid had been tied. The arteries on the left side of the brain were rather larger than those on the opposite side. The anterior cerebral artery was of the same size as its fellow: the middle cerebral larger than that on the right side, which was filled with coagulum and did not admit the injection. The large size of the latter vessel is accounted for by the increased size of the communicating branch; which receiving its blood from the basilary, had become as large as an ordinary radial artery. The basilary appeared to be of its usual capacity, although it was evidently the channel which supplied the middle cerebral artery. The blood probably found an easier course from the basilary, through the left communicating branch, than into the right corresponding vessels, which appeared rather diminished in size. From an inspection of the base of the brain after the vessels had been injected it immediately struck the observer, that the left side of the arterial circle of Willis was much more developed than the right, and that the left side of the brain received its full share of arterial blood. The anterior cerebral artery received its supply from its fellow by means of the transverse branch: these vessels seemed to be of their usual size. The

(*c*) Med.-Chir. Trans., vol. i. p. 222. 1809.

(*d*) Guy's Hospital Reports, vol. i. 1836.

internal carotid was pervious for about half an inch, and of its ordinary capacity. The external vessels were not so well displayed. Those of the face did not receive the injection. The common carotid trunk was impervious throughout its whole extent, being reduced to a mere cord. The external carotid was injected at its commencement: and the superior thyroideal was filled from the arteries of the opposite side; but beyond this the arteries were empty and therefore could not be satisfactorily traced. The free communication of the branches of the external carotids, in their natural state, affords an ample channel of supply, when the circulation in one is cut off. The aneurism must, as Sir Astley Cooper suspected, have been situated in the internal carotid artery. (p. 57.) The preparation of the carotid arteries of this case is in the Museum at St. Thomas's.]

1442. If an aneurysm be seated in the branches of the carotid, the tying of the affected artery must, if possible, be performed. This tying may also be required on account of other diseased conditions. We must therefore consider tying the external carotid, the lingual, the external maxillary, the temporal, the occipital, and the posterior aural. Tying the superior thyroideal artery will be mentioned in the treatment of *bronchocele.*

1443. *Tying the external carotid artery* is considered as one of the most difficult operations, on account of the vessel being surrounded with arteries, veins, and nerves, and therefore also it is usually recommended to tie the common trunk instead of it (*a*). It has, however, been performed successfully by Bushe (*b*), on account of aneurysm by anastomosis; by Mott (*c*) in removal of the lower, and by Lizars (*d*) in that of the upper jaw-bone.

Dietrich (*e*) has proposed the most convenient mode of operating; a finger's breadth from the lower edge of the lower jaw, at a distance of half an inch from the inner edge of the sterno-mastoid muscle towards the *larynx*, a cut should be made obliquely upwards, and parallel to the edge of the sterno-mastoid muscle, through the skin, cellular tissue, and *m. platysma myoides.* After the division of a thin layer of cellular tissue, the external cervical *fascia* appears, upon which run some veins, which are to be raised, and the *fascia* and the cellular tissue divided with the handle of the knife. The internal cervical *fascia* is then to be cut through with slight strokes of the knife, and, whilst the edges of the wound are held asunder with blunt hooks, the inner edge of the sterno-mastoid muscle appears on the outer edge of the wound; at its inner edge the tongue-bone is felt; at the upper angle of the wound are seen the submaxillary and parotid gland; at the under edge, the digastric muscle; and at the lower angle the omo-hyoid. With the greatest care the fat and cellular tissue filling the bottom of the wound must now be divided, keeping towards the upper angle of the wound, for the purpose of best avoiding the venous branches, to wit, the superior thyroideal, sublingual and facial, and thus the artery is exposed, partially covered by the common trunk of the facial veins. Now begins the most difficult part of the operation, to wit, the isolation of the artery from the surrounding important parts. At the upper angle of the wound the artery crosses the lower edge of the digastric muscle, as well as the principal trunk of the hypoglossal nerve, which runs parallel to the edge of the muscle; on the inside some twigs pass down from the hypoglossal nerve, and, at the same time, the superior thyroideal

---

(*a*) Manec, above cited, pl. iv.

(*b*) Lancet, 1827–28, vol. ii. p. 482.

(*c*) American Journal of Medical Sciences, vol. ix. 1845.

(*d*) Lancet, 1829–30, vol. ii. p. 54.

(*e*) Above cited, p. 186.

artery and vein run down from above to the internal jugular vein. The trunk of the facial veins lies in part upon the artery, and upon the wall of the artery descends a branch of the hypoglossal nerve. On the outside of the artery are the internal carotid artery, and the internal jugular vein, which frequently covers the latter artery; together with them descend the pneumo-gastric and sympathetic nerves, which divide into many branches. Between, and rather behind the two arteries, passes up with, and very near it, the ascending pharyngeal artery, from the external carotid. The laryngeal nerve, as well as branches of the hypoglossal nerve, cross it deeply, passing on the back and inner part inwards and upwards. The external carotid artery is best tied either above the giving off of the superior thyroideal, or where it crosses the lower edge of the digastric muscle. This muscle, and the hypoglossal nerve, must therefore be somewhat separated from the cellular sheath, and with the submaxillary gland drawn upwards with a hook by one assistant, whilst another draws the internal carotid artery, the internal jugular vein, and the nerves outwards. When the operator has now in part pressed the trunk of the facial veins lying on the artery, aside and inwards, he opens the sheath of the artery with the handle of the scalpel, and passes the ligature with DESCHAMPS' needle from without inwards.

1444. BECLARD (*a*) has proposed *tying the lingual artery* in bleeding after deep extirpation of the tongue, and the like. Tying it on one side is sufficient, as the bleeding from the other side of the tongue may be stanched by cauterization. The patient lies with his head somewhat bent back, and with his face turned towards the sound side; the operator thoroughly satisfies himself of the position of the tongue-bone, which, during the whole operation, must guide him, and makes a cut from an inch to an inch and a quarter long, which he commences a little behind the horn of the tongue-bone, and carries upwards and forwards, half an inch over the body of that bone. The skin and *m. platysma myoides* are thus divided, avoiding the facial vein, which is to be turned backwards. The cellular sheath of the submaxillary gland is then to be opened, and the gland raised without injuring it, upon which the digastric and stylo-hyoid muscles, as well as the hypoglossal nerve, appear. If these different parts be very near the tongue-bone, as happens with persons who have short necks, they must be gently raised, so as to expose the outer side of the hypoglossal muscle, some fibres of which are to be seized with the forceps, raised, the director introduced under them and then divided, upon which the artery is exposed, and easily isolated.

DIETRICH (*b*) makes the cut as in tying the external carotid artery, only with this difference, that he begins three lines from the under edge of the lower jaw, and carries it two inches downwards, through the skin, cellular tissue, *m. platysma myoides*, and external cervical *fascia*. The vein being avoided, and the second *fascia* divided, the edges of the wound are to be kept asunder with hooks, when the submaxillary gland and lower edge of the digastric muscle appear at the upper angle of the wound. The cellular tissue, connecting the gland with the muscle, is to be divided, and the gland raised up, which exposes the stylo-hyoideal muscle. Both muscles and the hypoglossal nerve are to be drawn downwards or upwards, and the two layers of cellular tissue being divided with the handle of the knife, the artery now appears close to the trunk of the external carotid artery, from which it is given off. In front of the artery passes the lingual vein; often, also, on its inner and outer side the facial vein; and still further, the superior laryngeal nerve. The nerve must be drawn down, the vein up, and the

---

(*a*) MANEC, above cited, pl. iii.—BELL, CHARLES, Operative Surgery, vol. ii. p. 307.—WISE; in AVERILL, above cited, p. 53.

(*b*) Above cited, p. 2

artery tied from below upwards, immediately above the great horn of the tongue-bone. If the artery is to be tied still more distant from its origin, it is not necessary to cut into the fleshy fibres of the hypoglossal muscle. The artery otherwise runs through sufficient extent before it passes under any muscle.

1445. The *external maxillary or facial artery is tied* at the angle of the lower jaw in the following manner. A cut is to be made on the inner edge of the masseter muscle, running obliquely downwards and outwards, to the extent of an inch or a little more through the skin, cellular tissue, and fibres of the *m. platysma myoides.* In this direction the cellular tissue and some threads of the facial nerve are cut through; and the edges of the wound being separated, the artery appears on the inner edge of the masseter muscle, lying on the *periostæum*; and close to it, on the outer side, is the facial vein; these are drawn outwards, and the artery isolated with ease.

This artery can be tied in its submaxillary part only with the greatest difficulty. Manec (*a*) declares himself against this operation, because the artery lies very deeply, and is covered by very many parts. Velpeau and Dietrich have given the modes of proceeding in this operation. By the former, an incision is made from the submaxillary gland to the inner edge of the sterno-mastoid muscle, and then a second from the hinder end of the great horn of the tongue-bone to the inner edge of the masseter muscle, through the skin and *m. platysma myoides*, and the flap so formed should be turned back upwards. The edges of the wound are to be kept asunder, the flap held up, and the now displayed *aponeurosis*, from which the artery is only separated by cellular tissue, must be cut through, in doing which the facial vein is sometimes divided, between the submaxillary gland and digastric muscle; after this the artery is to be isolated and tied between the great horn of the tongue-bone and the submaxillary gland. According to Dietrich, the cut should be made two lines from the under edge of the jaw, directly down, rather obliquely outwards and downwards, to the inner edge of the sterno-mastoid muscle. The facial vein is never to be cut through, but separated from the submaxillary gland, and carried outwards or inwards, as may be most convenient. The hypoglossal nerve is to be taken care of. The artery passes under the stylo-hyoid muscle, at the point where it is perforated by the digastric muscle, about half an inch from its insertion in the tongue-bone. The muscles together with the nerves, are to be separated from the cellular tissue, and carried downwards, and the ligature passed around the vessel from without inwards, and from below upwards.

1446. *Aneurysms of the temporal artery*, occurring after wounds, may be often cured by compression, as I have seen in one instance, when aneurysm occurred after arteriotomy; if this be not possible, the temporal artery must be tied. The position of the artery is to be first well ascertained by feeling with the finger, and then along its course a cut an inch in length is to be made through the skin, midway between the joint of the jaw and the auditory passage; a director is then to be introduced beneath the pretty thick cellular tissue by which the artery is covered, and this being divided, the artery is to be isolated. The accompanying vein lies to the outer side.

1447. *Aneurysms of the occipital artery* rarely occur, though Meyer (*b*) mentions a case in which, on account of aneurysm, many branches and the trunk of the occipital artery were tied. J. Burns (*c*) also tied this vessel for an aneurysmal swelling. A cut is to be made half an inch behind, and a little beneath, the tip of the mastoid process, and continued obliquely upwards and backwards, to the extent of an inch or an inch and a quarter. The skin and *aponeurosis* of the sterno-mastoid muscle are to be divided, and the finger carried under the upper lip of the wound, in order to feel the base of the mastoid process. The *m. splenius* is then to

---

(*a*) Above cited, pl. iv.

(*b*) Dissert. de aneurysmate arteriæ occipitalis 1804.—Scarpa, Translation, p. 199, note.

(*c*) In his brother's Surgical Anatomy of the Head and Neck, p. 374.—Manec, above cited, pl. v.—Dietrich, above cited, p. 209.

be divided the whole length of the wound, and the pulsation of the artery being felt, should be carefully isolated, so as not to injure the accompanying veins.

1448. *To tie the posterior aural artery*, a cut half an inch long should be made, from the lobe of the ear to the inner edge of the sterno-mastoid muscle, and continued upwards along its inner edge an inch upwards; this cut divides the skin, fatty cellular tissue, and the muscular *aponeurosis*. An assistant with a blunt hook separates the edges of the wound, and then is seen, at the lower angle of the wound, a portion of the parotid gland; but in the upper angle, the lower edge of the lower retractor of the auricle; in the middle of the wound the artery is to be sought for, isolated, and tied (*a*).

Syme (*b*) tied a branch of the posterior aural on account of aneurysm.

[Astley Cooper (*c*) had a case of "aneurism of the posterior aural artery from a blow; he opened the sac, and was compelled to tie, not only the vessel which led into the sac, but numerous others entering in all parts of the circumference of the swelling." (p. 82.)

Begin (*d*) gives the account of an aneurysm of the middle meningeal artery, in which the bone having been absorbed, the tumour became superficial, and, being mistaken for an encysted tumour, was extirpated. An ineffectual attempt was made to stop the bleeding by plugging; but the patient could not be saved.

The branches of the internal carotid artery within the skull sometimes become aneurysmal. A remarkable instance of this kind occurred to Dr. (afterwards Sir Gilbert Blane) (*e*), in a female of sixty-four years old, who "was suddenly seized with a fit of giddiness and dimness of sight, succeeded by acute pain in the forehead, which remained for some time. The indistinctness of vision continued for six months; after this, she was at intervals seized with giddiness, headache, and imperfect vision. She had a similar attack two years after the first, from which also she recovered to a certain degree. From this period she continued subject, from time to time, to the above-mentioned symptoms as long as she lived. She for some time saw objects double, but the particular period of this could not be ascertained." (pp. 193, 94.) She afterwards betrayed signs of mental derangement, and became maniacal, and died in that state five years after her first attack. On *examination* there was found more water than usual in the ventricles of the brain; upon the *falx*, some *spicula* of bone; and the optic nerves were smaller than usual, as if they had been wasted." The morbid appearance in this case, which was so singular, and to which the symptoms of complaint seemed chiefly referable, was to bulbs about five-eighths of an inch in diameter, filling up the hollow on each side of the *sella tursica*, which were evidently dilatations of the carotid arteries, and, from their being filled with *laminæ* of coagulated blood, there could be no doubt of their being aneurisms of these arteries. The one on the left side was the largest; that on the right communicated with the cavity of the artery, which was not the case with the other." Blane observes:—"It is probable that one of the aneurisms arose five years before her death, occasioning the first attack described, and that the other arose two years afterwards, occasioning the other attack. It is also probable that it was between these two attacks that she saw objects double, from the unequal compression on the optic nerves." (pp. 196, 97.) Hodgson mentions an instance of a small aneurysm in the anterior cerebral artery, filled with a solid coagulum, and another in the basilar artery was seen by Serres.]

II.—OF ANEURYSMS OF THE SUBCLAVIAN AND AXILLARY ARTERIES.

1449. Aneurysm of the axillary artery in general increases quickly, as the surrounding parts offer little opposition. The swelling raises the great pectoral muscle, spreads towards the collar-bone, and thrusts it upwards. It is, therefore, rarely that this aneurysm is so early observed, that there

---

(*a*) Dietrich, above cited, p. 211.

(*b*) Edinburgh Med. and Surg. Journ., vol. xxxi. p. 66. 1829.

(*c*) Surgical Lectures.

(*d*) Dictionnaire de Médecine et de Chirurgie pratiques, vol. ii. p. 533—article, *Anévrysme*.

(*e*) History of some cases of Disease in the Brain; in Trans. of a Society for the Improvement of Med. and Chir. Knowledge, vol. ii. 8vo. 1800.

is still space sufficient (*a*) for tying the axillary artery, and this operation is usually possible only in aneurysms at the upper part of the brachial artery.

1450. *Tying the axillary artery* may be performed in two situations, namely, *first*, by cutting through the great pectoral muscle, under the collar-bone; and *second*, by division of the tendinous interspace between the pectoral and deltoid muscles. The patient either lies on a bed or sits on a sloping chair, with the shoulders somewhat depressed; an assistant stands behind, and is ready to compress the subclavian artery, if bleeding should occur during the operation.

1451. In the *first mode* of operating, a cut must be made through the skin, commencing an inch from the sternal end of the collar-bone, and continued along its under edge towards the coracoid process of the blade-bone, as far as the cleft which separates the pectoral and deltoid muscles. In this direction the connexions of the great pectoral muscle with the collar-bone are divided, and thus the lesser pectoral muscle is exposed, which, beginning from the coracoid process, crosses the lower angle of the cut. The point of the finger is then to be introduced between the coracoid process and the lower edge of the collar-bone, and the artery is there found surrounded, upon the outer side, and partially covered by the brachial *plexus*, and upon the inner side by the brachial vein. The artery is now to be carefully separated from the vein and nerves, and a single ligature carried round it with Deschamps' needle, before withdrawing which, the artery should be compressed upon it, for the purpose of ascertaining that it alone is taken hold of. The small arteries wounded during the operation are to be tied at once, and the wound kept clear of blood. The dressing and after-treatment are to be conducted according to the former general rules.

The direction of the wound in this mode of operation is variously advised. The most important variations are—that recommended by Lisfranc, in which the cut is commenced half an inch from the sternal end of the collar-bone. in the pit formed by the clavicular and sternal parts of the great pectoral muscle, and carried three inches below the collar-bone; and the practice recommended by Zang and others, who carry the cut close beneath the collar-bone, beginning from its middle, and continue it for two and a half inches downwards and outwards, nearly to the coracoid process.

1452. In the *second mode* of treatment, if the artery be not tied so near the collar-bone, a cut is made of two and a half inches length, from the lower edge of the outer third of the collar-bone, towards the inside of the upper arm, on the interspace between the great pectoral and deltoid muscles. The lesser pectoral muscle is cut off at its insertion to the shoulder-blade. The forefinger is now to be carried deeply into the wound, and passed upon the surface of the *m. serratus magnus*, till its tip reach the shoulder-blade. The finger is now curved, and, following the inner surface of the subscapular muscle, is again carried forwards, up to the outer lip of the wound in the skin. In this way is the whole armpit swept round, and the entire mass of vessels and nerves, collected immediately under the collar-bone, are without difficulty brought to the external parts between the edges of the wound, and fixed with the finger. Here the artery is easily isolated and tied (*b*).

[The operation of tying the axillary artery in either mode above recommended, or indeed in any other way, has not met with much favour among practical Surgeons; the position of the vein so much in front of it, and its almost complete envelopment by the

(*b*) Delpech, Chirurgie Clinique de Montpellier, vol. i.

axillary nerves, together with its great depth, render it a very hazardous and difficult operation. As to dragging up the whole mass of vessels and nerves to the surface, and then selecting the artery to be tied, as recommended by Delpech, no person who had had any experience in tying arteries, would think of doing, on account of the necessary detachment of the vessel from its connexions, which would put it into a very unfavourable condition for the effusion of adhesive matter on its exterior, and interfere with its healing up. And indeed, though this might be done on a vessel undiseased, yet if any aneurysmal swelling existed, there would not be room to attempt it. Nor is there any good reason to perform so troublesome and dangerous an operation, when tying the subclavian above the collar-bone will answer all the purposes required, with greater ease and safety. If the artery were wounded and its ends exposed, as in Hall's case, related by J. Bell (a), and Maunoir's case, mentioned by Scarpa (b), then tying the ends of the wounded vessel would, as under ordinary circumstances, be required. But for aneurysm of this vessel, tying the subclavian is always preferable.—J. F. S.]

1453. If an aneurysm situated upon the commencement of the axillary artery, or at a deep part of its commencement, so extend, that it reach the collar-bone, the *subclavian artery must be tied above the collar-bone.* The patient being seated on a chair, or laid horizontally upon a table, and the shoulder of the ailing side depressed as much as possible, a cut is made through the skin, extending from the outer edge of the sterno-mastoid muscle, along the collar-bone, to the clavicular insertion of the *m. trapezius.* Then the *m. platysma myoides* is to be divided carefully in the same direction, so that the external jugular vein may not be wounded, which, when laid bare, is to be drawn towards the shoulder with a blunt hook. The cellular tissue in the midst of the wound is next divided with the knife, or more safely with the finger, or a director, till the edge of the *m. scalenus anticus* be reached with the finger, where the artery is found lying on the first rib, and the ligature is to be carried round it with Deschamps' or Desault's needle.

The cut for tying the subclavian artery, should, according to Zang, be made in the middle of the triangle, formed by the hind belly of the *m. omo-hyoideus,* and the hind edge of the clavicular part of the *m. sterno-cleido-mastoideus,* and should be commenced two inches above the collar-bone, at the hind edge of the latter muscle, and carried somewhat obliquely outwards and downwards to the middle of the collar-bone.

I have found this operation easiest on the dead subject; the subclavian vein lies on the inside of the artery, the nervous *plexus* on the outside, and partially covering it. A little stud on the first rib, which is felt at the inner side of the artery, and the hollow made by the artery in that rib, are given as the certain marks for directing the finger upon the artery. Taking up this artery is often extraordinarily difficult, and even impossible (c), if, from the size of the swelling, the collar-bone be very much thrust up; the operation should therefore always be performed early. The same also happens in tying the ligature for which Liston (d) has proposed a peculiar contrivance. As the artery is partially covered with the *plexus* of nerves, one of the nerves may be taken up and tied instead of the artery, as pulsation is propagated to it (e).

In one case where the ordinary mode of treatment was inapplicable, Dupuytren (f) cut through the *m. scalenus anticus.* Hodgson, Lisfranc, and Graefe, have proposed the same in their modes of practice, that, after a long cut has been made through the skin and the *m. platysma myoides,* from the hind edge of the sterno-mastoid muscle, from two to two and a half inches along the collar-bone, the operator should dip deeply, and seek for the *m. scalenus anticus,* pass beneath it a curved director, raise it up, and cut it through either from without inwards, or carefully across, without previously introducing a director.

[The operation of tying the subclavian artery above the collar-bone was first attempted by Astley Cooper in the spring of 1809, but "the aneurysm was very large, and the clavicle was thrust upwards by the tumour, so as to make it impossible to pass a ligature under the artery, without incurring the risk of including some of the nerves of the axillary *plexus*. The attempt was therefore abandoned" (*a*). The operation was first performed in St. Bartholomew's Hospital, *Nov*. 2, 1809, by Ramsden (*b*), for axillary aneurysm about half the size of a large orange. He first made a transverse cut through the skin upon the collar-bone, two and a half inches long, from the outer border of the *m. trapezius*, to within half an inch of the outer edge of the *m. sterno-mastoideus ;* and then pinching up the skin above the bone, he divided it, from within, outwards and upwards, in the line of the outer edge of the sterno-mastoid muscle to the extent of two inches. His object in pinching up the skin for the second cut "was to expose at once the superficial veins, and by dissecting them carefully from the cellular membrane, to place them out of the way without wounding them." (p. 282.) He then dissected with his knife till he had brought into sight "the anterior *scalenus* muscle immediately below the angle which is formed by the traversing belly of the *m. omo-hyoideus*, and the edge of the *m. sterno-cleido-mastoideus ;* and having placed his finger on the artery, at the point where it presents itself between the *scaleni*, he found no difficulty in tracing it without touching any of the nerves, to the lower edge of the upper rib, at which part he detached it with his finger-nail for the purpose of applying the ligature." (p. 283.) Various kinds of instruments, fixed in handles, were essayed in vain to pass the ligature, which was at last managed with a flexible probe, the end of which being introduced behind the artery, was drawn out with the forceps, and the operation completed with a single ligature. The patient died after five days. The subclavian artery was next tied by Sir William Blizard, in 1811, in the London Hospital, but the patient died on the fourth day; by Thomas Blizard, in 1815, but death followed on the eighth day (*c*); in the same year, by Dr. Colles, of Dublin, but the man died on the eighth day (*d*); The first successful case was that of Dr. Post, of New York, who operated on *Sept*. 8, 1817; the aneurysmal tumour burst on the *ninth* day, and discharged above three ounces of blood; the ligature came away on the *eighteenth* day (*e*). The second successful case was Liston's, in which the operation was performed on *April* 3, 1820; the ligature came away on the twelfth day (*f*). Since this time favourable results have frequently followed ligature of the artery at this part, by English Surgeons, Gibbs of St. Petersburg, Bullen of Lynn, Wishart of Edinburgh, Green at St. Thomas's, twice, Key and Bransby Cooper, each at Guy's Hospital, and Hobart of Cork.

Green, in his operations, made a similar cut above the collar-bone, with its concavity upwards, and the inner end higher than the outer; and, in the case referred to at *page* 224, the external jugular vein being in the way, he put two ligatures upon it, about an inch above the collar-bone, and divided between them, which gave much additional room. To avoid the difficulty often experienced in passing the ligature round the artery, instead of using the common aneurysmal needle, either with or without a handle, and which difficulty appears to arise from the too great length of the curve of the needle, he employed a needle, the curve of which, in size and shape, nearly resembled an ordinary button-hook, and with this the ligature was readily passed round the vessel.

In taking up the artery care should be taken that the ligature be not passed round one of the nerves instead of the artery: this mistake occurred to both Liston and Green, but was quickly discovered and corrected. An occurrence like this happening to such able and excellent Surgeons will show the necessity of extreme caution before tightening the ligature. I recollect also having seen, on one occasion, the posterior scapular artery, as it crossed the space between the sterno-mastoid and trapezial muscles, being mistaken for the subclavian, and tied, but this mistake was quickly discovered, and the subclavian immediately found and tied.—J. F. S.]

1454. If the aneurysm be situated in the subclavian artery itself, *tying that artery on the tracheal side of the m. scalenus* may, perhaps, give hope of a cure. This operation must, however, always be considered as extremely dangerous and hazardous, if it be remembered with what important structures the artery is connected. The pneumo-gastric and phrenic nerves lie before it, the lower cervical ganglion and sympathetic nerves behind it;

on the right side, the recurrent laryngeal runs round it, and upon the left, lies between it and the gullet; the subclavian vein lies immediately beneath the collar-bone before the artery, and when distended, even upon it; and it rests immediately upon the *pleura*, which, in carrying round the needle, may be easily wounded. If the ligature be applied in the neighbourhood of the origin of the inferior thyroideal, internal mammary, and vertebral artery, the formation of a plug is prevented, and secondary bleeding ensues (*a*). It is also to be further remembered, that aneurysm of the *aorta*, or of the *arteria innominata*, frequently rises so much above the collar-bone (1), that it may be easily mistaken for subclavian aneurysm (*b*). A. COOPER, COLLES, ARENDT, MOTT, and HAYDEN, have performed this operation, but not successfully in any case.

The proceeding in this operation is as follows:—A cut three inches in length is to be made through the skin, and *m. platysma myoides*, immediately above the sternal end of the collar-bone; a director should be passed under the clavicular origin of the sterno-mastoid muscle, which is to be divided from the bone, or according to HODGSON and ARENDT, the sternal origin also. The cellular tissue is then to be divided with the finger, or with the handle of a knife, till the tracheal edge of the *m. scalenus anticus* is reached, behind which the artery is felt passing. It will be advisable to draw the artery forth, so that the ligature may be applied beneath the origin of the inferior thyroideal and vertebral arteries. When the artery is surrounded by the aneurysmal needle, very great care must be taken not to wound the *pleura*, nor to include any other structure.

DIETRICH (*c*) has proposed a modification of KING's operation for the right and left side. Upon the *right* side a cut is to be made from the middle of the semi-lunar notch in the top of the breast-bone upwards, directly in the middle line of the windpipe. He then penetrates, in the same way as he proceeds in tying the *arteria innominata*, into the interspace between the two sterno-hyoideal muscles, till he comes to the bifurcation of the subclavian artery. The sterno-hyoideal and sterno-thyroideal arteries are now to be drawn outwards with a blunt hook, and the sheath of the artery carefully slit up, till the pneumo-gastric nerve and internal jugular vein be seen descending immediately before the artery. Upon the *left* side, a cut is to be made on the inner edge of the sterno-mastoid muscle, a line from it, nearer the windpipe, which shall extend for two and a half inches up, along its inner edge, but so, that it is always a line's breadth distant from it. A transverse cut of half an inch, is then to divide the skin and sterno-mastoid muscle. The cellular tissue in the wound is to be carefully divided, any irregular vein, if cut through, to be tied, and the divided sternal portion of the sterno-mastoid muscle drawn towards the left shoulder, with a blunt hook, by an assistant. The outer edge of the sterno-thyroid muscle now appearing, the cellular tissue connecting the underlying parts is now to be somewhat loosened, and drawn by an assistant towards the right side. The carotid artery then appears in the wound, the internal jugular vein in its outer side, and the pneumo-gastric nerve between them. In the lower part of the wound, opposite the base of the breast-bone, behind, and to the outer side of the carotid, lies the subclavian artery. The internal jugular vein is now to be carefully separated from the pneumo-gastric nerve and carotid artery, and drawn back with a blunt hook towards the shoulder by an assistant, who also draws the sternal portion of the muscle in the same direction. The subclavian artery, enclosed in its thick cellular sheath, now becomes visible; its branches, the inferior thyroideal, transverse cervical, vertebral, and internal mammary, are given off somewhat above. The thoracic duct, which here forms its curvature, lies on the inner edge of the sheath of the artery, and also behind the carotid. The artery is now to be somewhat isolated with the handle of the scalpel, the sheath opened on the outside with a careful stroke of the knife by which injury of the thoracic duct is best avoided, and then with a curved blunt hook the ligature should be carried round the artery from behind forwards, and from above downwards.

(*a*) HODGSON, above cited, p. 381.

(*b*) BURNS, A., above cited, p. 30. (*c*) Above cited, p. 43.

[(1) In reference to this most important point it may be mentioned, that there are in the Museum at St. Thomas's Hospital two preparations. The one, an aneurysm of the arch of the *aorta*, involving part of the *arteria innominata*, and mistaken for carotid aneurism; a parallel instance to Allan Burns's case. The other, an aneurysm from the curvature between the origins of the left carotid and subclavian arteries, which communicated by a narrow canal with a large bag in the neck, and having the carotid artery behind it. The latter was the case to which Astley Cooper referred, when advising Burns to be cautious in undertaking a proposed operation for a pulsating tumour above the clavicle, which was at first thought to be a subclavian aneurysm. In the Museum at Fort Pitt, Chatham, there is a preparation of an aneurysm as large as a walnut between the origins of the *arteria innominata* and left carotid. And also another, bounded by the brachio-cephalic trunks in front, the sac of which is deeply indented by the *arteria innominata*.—J. F. S.]

1455. Allan Burns (*a*) and Hodgson (1) proposed *tying the arteria innominata*, and showed, by injecting the dead body, that the circulation can be supported after the obliteration, and that on the subject, the operation can be performed without great difficulty, if the head be bent back, the sternal portion of the sterno-mastoid, sterno-thyroid and hyoid muscles be separated, and the artery followed to its origin. Mott (*b*), Graefe (*c*), Arendt (*d*), Hall (*e*), Bujalsky, Bland, and Lizars (*f*), have performed this operation on the living subject, but not successfully.

In Mott's case, the patient died on the twenty-sixth day, in Graefe's, on the sixty-seventh, and in Arendt's, on the eighth day; in the two former cases from repeated bleeding, and in the third, in consequence of severe inflammation of the aneurysmal sac, of the *pleura*, and lung. Mott, beginning from the aneurysmal swelling, made a cut above the collar-bone, lengthened it to that bone, and continued it on the windpipe, above the upper end of the breast-bone. From thence he made a second cut of about the same length, and carried it along the inner edge of the sterno-mastoid muscle. He then separated the skin from the *m. platysma myoides* beneath it, cut through the latter, and carefully separated the sternal part of the sterno-mastoid muscle in the direction of the former cut. The internal jugular vein, which had adhered to the swelling, was now separated, the sterno-hyoid, and sterno-thyroid muscles cut through, and turned back over the air-tube. The carotid now laid bare for some lines above the breast-bone, was separated from the pneumo-gastric nerve, and the internal jugular vein, which were drawn to the outer side. He now exposed the subclavian artery, in which he particularly used the handle of the scalpel, and a small narrow knife, with a rounded cutting end. In this way he penetrated to the division of the *arteria innominata*, following it under the breast-bone, freed it with the handle of the knife from all the surrounding cellular tissue, and after drawing the recurrent and phrenic nerve aside, he applied a round silk thread around the artery, about half an inch above its division.

Graefe makes an incision on the inner edge of the sterno-mastoid muscle two inches long, and continues it two inches downwards upon the first portion of the breast-bone. He then separates the lips of the wound with blunt hooks, and passes the fore-finger of his left hand, between the sternal part of the sterno-mastoid and sterno-hyoid muscles, not further than the top of the breast-bone, separating the cellular tissue up to the

---

(*f*) Lancet, 1836-7, vol. ii. p. 445, p. 602.

carotid artery. The patient's head is to be then bent much backwards by an assistant, and the operator carries his finger down along the carotid. Having reached the inner surface of the top of the breast-bone, he finds a blue swelling, under which his finger must be introduced. With the aid of his finger, and the handle of the scalpel, he proceeds down to the place where the *arteria innominata* divides into the carotid and subclavian arteries. Then continues for half an inch farther down, takes the hook, armed with a thread, in the right hand, passes it close to the finger of the left hand, down to the *arteria innominata*, and carrying it round it, draws the threads, and applies **Graefe**'s ligature-apparatus.

Mott used the instruments employed by **Parish**, **Hartshorne**, and **Hewson** (*a*), which he recommends as sufficient for tying deep arteries. He carries a blunt-ended needle, having two eyes at the two ends, with a needle-holder, around the artery, carefully avoids the *pleura*, then introduces a hook into the eye of the needle, which is brought into view, with which, after freeing the needle-holder, he draws the needle out, and with it the ligature, which is then to be gradually drawn together and tied with two single knots. No effect upon the heart or lungs was noticed.

[(1) **Chelius** is mistaken as regards **Hodgson** on this point, for he neither proposed nor advised this operation. He merely quotes the operation proposed by **Burns**, and as to his opinion of it he observes :—" The ligature of the *arteria innominata*, or of the subclavian artery, on the tracheal side of the *scalenus*, must be regarded as peculiarly hazardous. I have thought it proper, however, to treat of these operations, because, under particular circumstances, a Surgeon may conceive it his duty to undertake them." (p. 384.)—J. F. S.]

1456. Besides these operations performed on living subjects, **Bujalsky**, **King**, **Dietrich**, and **Manec**, have proposed other methods for tying the *arteria innominata*.

According to **Bujalsky**, the cut through the skin should be made on the inner edge of the sternal portion of the sterno-mastoid muscle, between it and the windpipe, as long as the breadth of four fingers, a little to the inner side of the muscle above, commencing at the middle of the neck, and extending down to the middle of the notch of the breast-bone. The fibres of the *m. platysma myoides* are now apparent at the upper angle of the wound, but at the lower, there is a considerable quantity of fat. The cut is to be continued deeper, and in the middle of the wound the sterno-hyoid muscle is exposed, and to be cut through obliquely; beneath it is the sterno-thyroid muscle, which is also to be divided. The operator should keep as much as posssible to the inner edge, because the internal jugular vein runs along the outer edge. The inferior thyroideal vein, which in the wound passes obliquely under the muscles, is to be drawn upwards or downwards. Sufficient depth having now been attained, the artery is to be isolated and tied.

In **King**'s (or, rather, **O'Connell**'s) mode, a cut from fifteen to eighteen lines long is to be made on the inner edge of the sterno-mastoid muscle of the *left side*, through the skin, *m. platysma myoides* and *fascia* of the neck; the finger is then passed between the sterno-thyroid muscles, and under the right of those muscles, the cervical *fascia* divided, the finger introduced beneath it, and carried down to the *arteria innominata* lying upon it.

Dietrich has correctly shown the impracticability of **King**'s operation, and proposes the following. The patient's head should be bent a little backwards, and a cut of from two and a half to three inches long, according as the neck is longer or shorter, and more or less fat, should be made

---

(*a*) Eclect. Repos., vol. iii. p. 229.

from the middle of the base of the breast-bone directly upwards, in the mesial line of the windpipe. After dividing the cellular tissue and *fascia*, several little veins appear, enclosed in loose cellular covering; these may very easily be put aside, as they run in the same direction as the windpipe, and terminate in a large vein, which is visible at the lower angle of the wound. The cellular tissue is to be removed, and now the internal cervical *fascia* appears; on both sides lie the sterno-hyoideal muscles, separated by an interspace of two or three lines, and the *fascia* occupying it being cut through, the windpipe is reached. With a blunt hook the right sterno-hyoid, and sterno-thyroid muscles, are to be drawn outwards, which exposes the second inferior thyroideal vein, in the bottom of the wound, sometimes considerably expanded. If it be of the usual size, the point of the scalpel should be carried on its outer side, and the fatty cellular tissue carefully divided, the handle of the scalpel carried downwards, and so the *arteria innominata* reached. But if this vein be considerably enlarged, it must be got under from within outwards, and the cellular tissue in that way divided; this, however, must only be done with the handle of the knife, as otherwise there is no safety against wounding it, which is here of the greatest importance, as this vessel empties itself into the *vena cava descendens*, and, if wounded, severe bleeding would occur from the reflux of the blood. The hook is to be carried under the artery from left to right.

Manec (*a*) directs the head of the patient to be bent much backwards, so that the neck shall be greatly stretched, and the vessel to be tied brought up to the upper edge of the breast-bone; and the face is to be inclined a little towards the left shoulder. A cut of three inches' length is to be made from the middle of the space dividing the two sterno-mastoid muscles, towards the right shoulder, half an inch above the collar-bone, through the skin and *m. platysma myoides;* in the same direction the sterno-mastoid muscle is to be divided, and a director having been passed under the sterno-hyoid and sterno-thyroid muscles, they also are to be divided. For isolating the artery, the operator uses only the handle of the knife. If the inferior thyroideal vein, and some fibres of the hypoglossal and first cervical nerve require division, this must be done with the knife. The artery is to be isolated at its outer and back part with great care, so as not to injure the *pleura*. After this is done, Deschamps' needle should be introduced from the outside, between the pneumo-gastric nerve and the *pleura*, carried out upon the other side between the artery and the windpipe, and the ligature then drawn in.

1457. When the entire trunk of the subclavian artery is obliterated, the blood flows from the superior thyroideal and occipital arteries, into the inferior thyroideal, cervical, transverse scapular, and numerous anastomoses, which spread over the neck and shoulder, into the subscapular, supra-scapular, and posterior-scapular arteries, from which it passses into the trunk of the brachial artery. If the obliteration be at the lower end of the subclavian, or at the axillary artery, the passage of the blood is much more ready, as it is carried by the anastomoses of the cervivical, transverse cervical, and transverse scapular arteries, with the branches of the subscapular and posterior-scapular into the brachial artery (1). That in many cases, after tying the axillary artery for a wound, the sensation and nourishment of the arm are injured, depends not on the

---

(*a*) Above cited, pl. ii.

too small flow of blood, but on the injury of the *plexus* of nerves, caused by the wound, or by the tying (2).

(1) The following is the account of the mode in which the circulation was maintained in a case of axillary aneurysm, for which KEY had tied the subclavian artery twelve years previously (*a*); the circumstances of which had been already described (*b*). "The subclavian trunk had undergone no material alteration in size from its origin to the point where the ligature had been applied, just on the outer edge of the *scalenus* muscle. Here the vessel became suddenly obliterated, assuming the form of a dense flattened cord, which was continued for about two inches and a half into the *axilla*, and terminated in the remains of the aneurismal sac. The precise spot where the artery had been tied was clearly indicated by a deep indentation; but the continuity of the vessel above the ligature with the obliterated portion below it, was not destroyed, or, more properly speaking, had been restored, after the separation of the silk, by a process of adhesion, which connected the two extremities to each other, and glued them to the contiguous structures. The aneurismal sac still existed in the *axilla*, where it formed a firm and solid, but at the same time somewhat elastic and yielding tumour about the size of a small hen's egg, * * * and presented a smooth uniform exterior, bearing altogether considerable resemblance to those cysts which are occasionally found to form themselves around foreign bodies. The obliterated portion of the axillary trunk terminated in the upper and back part of the sac; while, from its under surface, the continuation of the artery was seen to emerge as a perfect vessel; having been restored to nearly its natural calibre by the entrance of a large branch, which was originally given off immediately below the tumour, and through which the blood had afterwards assumed a retrograde course. On opening the sac, the coats of which were remarkably dense and hard, it was found to contain a firm and solid coagulum, which readily separated from the surrounding cyst, and on being removed, retained the precise shape of the tumour. A section of it clearly evinced that it consisted of fibrin, apparently inorganized, dense and tough in its texture, and of a dirty-yellowish colour." The anastomosing vessels consisted of three sets:—"1. A posterior set, consisting of the suprascapular and posterior scapular branches of the subclavian, which anastomosed with the infrascapular from the axillary. 2. An internal set, produced by the connexion of the internal mammary on the one hand, with the long thoracic arteries and the infrascapular on the other. 3. A middle or axillary set, which consisted of a number of small vessels derived from branches of the subclavian above, and passing through the *axilla* to terminate either in the main trunk, or some of the branches of the axillary below. This last set presented, most conspicuously, the peculiar character of newly-formed, or rather dilated, arteries. They were excessively tortuous and formed a complete *plexus*, which was almost inseparably connected with the axillary nerves; many of the branches penetrating into the midst of the nervous fibres, so as to render their separation a work of great difficulty and labour. The chief agent in the restoration of the axillary trunk below the tumour was the infrascapular artery, which communicated most freely with the internal mammary, suprascapular, and posterior scapular branches of the subclavian; from all of which it received so great an influx of blood, as to dilate it to three times its natural size. The infrascapular artery was, in this subject, given off much higher than usual; and its origin had been included in the aneurismal dilatation; in fact the artery opened into the sac itself; and, under the restored state of the circulation, the blood had to traverse a small portion of the cavity in order to reach the commencement of the axillary trunk. The continuity between the two vessels had been preserved through the *coagulum* contained in the tumour, which, for a short space, actually constituted the arterial coats; thus, when the contents were removed, the injected wax became exposed at the bottom of the cyst; while a corresponding deep *sulcus* in the *coagulum* indicated the channel through which the blood had passed. The suprascapular artery was, in this instance, given off by the superficial cervical, and became augmented just as it reached the *scapula*, by a branch which arose from the obliterated portion of the main trunk, but which had again been rendered available, as a medium of circulation, by receiving a vessel from the subclavian above. The common origin of the short thoracic and humeral-thoracic arteries had become obliterated as it came off from the sac itself; but the two vessels had subsequently regained their original size; the one being supplied by its connexion with the internal mammary, the other by communications with the superficial cervical." (p. 63–5.)] This preparation is in Guy's Hospital Museum.

(*a*) Guy's Hospital Reports, vol. i. 1836.

(*b*) Med.-Chir. Trans., vol. xiii. p. 1. 1827.

(2) Not only do weakness and numbness occur when the axillary nerves are injured, but even gangrene has happened in the case mentioned by White, of Manchester (*a*), in which three of the nerves were tied in, and in Desault's case (*b*), in which the whole axillary *plexus* was included in the ligature.—J. F. S.]

1458. The tying of two branches of the subclavian artery, to wit, the internal mammary, and the vertebral artery have yet to be mentioned.

1459. The *internal mammary artery may be tied* without much difficulty in the second, third, or fourth intercostal space; in the first, its nearer position to the edge of the breast-bone renders its tying more difficult. In either of the just-named intercostal spaces, a cut made from the edge of the breast-bone, and on the upper edge of the lower rib, is carried outwards, and a little upwards towards the lower edge of the upper rib, so that its whole extent occupies an inch and a half, and by its termination, just below the under edge of the upper rib, it is secured from injuring the intercostal artery. The skin, cellular tissue, and *aponeurosis* of the great pectoral muscle are to be divided, and also the muscle itself. There still appear some layers of cellular tissue, and beneath them the *ligamenta nitentia*; these are to be divided with some slight strokes of the knife, as well also as some fibres of the intercostal muscles hereupon seen, with which usually a small arterial branch is cut through, and must be at once tied. A thin layer of cellular tissue still covering the artery is now to be carefully divided, the artery isolated from the accompanying vein, and a needle carried round it, from within outwards. In the third and fourth interspace the artery lies upon the fibrous expansion of the *m. triangularis sterni*; so that, in carrying round the needle, there is no fear of wounding the *pleura* (*c*).

Velpeau's practice of making a cut three inches long, parallel to the side edge of the breast-bone, and which must be deepened to get at the artery, is unfitting. On the contrary, I have very frequently found the artery by a cut, commencing on the side edge of the breast-bone, and running directly in the middle of the costal interspace, more frequently than in the way just described.

1460. For the possible case of *tying the vertebral artery*, Dietrich (*d*) has proposed two modes of treatment, according as the artery is to be looked for between the *atlas* and dentate *vertebra*, or between the *atlas* and occipital bone.

In the *former* case, the head of the patient being inclined to the opposite side, and a little forwards, a cut is to be made two fingers' breadth from the lobe of the ear, or one finger, behind the mastoid process, beginning half an inch above the latter, and carried for two inches along the outer hinder edge of the sterno-mastoid muscle. From the upper fourth of the length of this cut, a second is to be carried backwards, and obliquely downwards, to the extent of an inch. After dividing the skin, some cellular tissue appears in both cuts, which should be divided, and then in the first is seen the outer and hinder edge of the sterno-mastoid muscle; and in the second, the *m. splenius* covered with aponeurotic expansion. The wound is now to be deepened, through the aponeurotic and cellular tissue, and in the second cut the fibres of the *m. splenius* are to be divided, at which time a small artery will be wounded. After the division of this muscle a second aponeurotic layer appears, which must be divided with some light strokes of the knife, and under it pass some branches of arteries and nerves. An assistant with blunt hooks holds the edges of the wound apart, and now a layer of fat appears, in which the vertebral artery is

(*a*) London Medical Journal, vol. iv. p. 159.

(*b*) Œuvres Chirurgicales, vol. ii. p. 553.

(*c*) Dietrich, above cited, p. 89,

(*d*) Ibid., p. 81.

enveloped. At the same time also the outer edge of the *m. obliquus capitis inferior* is seen at the inner edge of the second wound, and is to be drawn somewhat inwards. Two branches of the occipital artery, also enclosed in cellular tissue, pass across the wound. The cellular tissue is now to be divided with the handle of the knife, and the arterial branches drawn upwards or downwards. Two branches of the second cervical nerve also now show themselves, and are to be drawn up or down out of their place; after which the isolation of the artery is no longer prevented. This done, the needle is to be carried round the artery from without inwards, in order more certainly to avoid the internal carotid artery, which lies very near the vertebral, and is only separated from it by cellular membrane.

If the vertebral artery be tied between the *atlas* and *occiput*, the cut should be made, as in the former case; but the first is to be begun a quarter of an inch above the mastoid process, by which the second cut, which, in like manner, passes from the upper fourth of the length of the former backwards and obliquely downwards, runs somewhat more upwards. After cutting through the skin, *fascia*, and *m. splenius*, the occipital artery appears in the upper angle of the first wound, as also at the front edge on the upper fourth, the hind edge of the *m. obliquus capitis superior;* but in the whole surface of the wound a layer of *aponeurosis*, and under it cellular tissue, loaded with fat, the former of which must be carefully divided. The edges of the wound are now to be held asunder with blunt hooks by an assistant, and then a triangle appears, formed by the *m. rectus capitis posterior*, and *m. obliquus capitis superior* and *inferior*, filled with fat and cellular tissue, which covers the artery. This is then to be carefully divided, turned back, and, if in large quantity, should be partially removed, upon which the artery appears below the *m. obliquus capitis superior*, and runs backwards nearly an inch before it perforates the occipito-atlantal ligament. The vessel is then to be isolated, and the ligature, by the aid of a ligature-needle, passed obliquely from below upwards, for the purpose of more surely avoiding the nerves and vein.

Nuntiante Ippolito, who saw two cases of aneurysm of the vertebral artery, has proposed the following mode of tying it. After having found the triangular space formed by the external jugular vein, the hind edge of the sterno-mastoid muscle, and the upper edge of the collar-bone, a cut is to be made through the skin, from its top to the base, not exceeding two inches in length. The operator continues penetrating in this direction till he reach the inner edge of the *m. scalenus anticus*, and thus the artery is easily struck upon, without injuring one twig of a nerve (*a*).

Möbus (*b*) mentions a case of aneurysm of the vertebral artery, originating in wound which was cured by compression, the application of ice, and so on.

[An example of this very rare disease (aneurysm of the vertebral artery) has recently occurred in the Northern Infirmary at Liverpool; the carotid artery could be distinctly traced over the pulsating swelling, of the actual nature of which there were some doubts, as to what kind of aneurysm it was, or whether only a pulsating tumour. It was decided to tie the common carotid artery. The tumour rapidly increased after the operation, and in about a fortnight the patient died by bursting of the aneurysm into the trachea. On *examination*, an aneurysm of the vertebral artery, between the transverse processes of the fourth and fifth cervical *vertebræ* was found.—J. F. S.]

Upon the importance of tying the vertebral arteries, and its greater danger in comparison with tying the carotid arteries in animals, see Astley Cooper (*c*).

[The arteries of the brain sometimes become affected with aneurysm. In the Museum of the Royal College of Surgeons, there is an example of a small conical aneurysm in the anterior cerebral artery.—J. F. S.]

III.—OF ANEURYSM OF THE BRACHIAL, ULNAR, AND RADIAL ARTERIES.

1461. Aneurysms of the brachial artery, and its branches, are almost always consequent on wounds, and occur most frequently at the bend of the arm, after a wound of the artery in bleeding. In these aneurysms therefore compression is commonly employed with the best results.

["I do not recollect," says Astley Cooper, "to have seen a case of aneurysm from disease in the brachial artery." (p. 78.) Hodgson observes:—"I have never seen an aneurysm in the arm which was not produced by accidental violence." (p. 389.) Liston (*a*) also speaks of the rarity of spontaneous aneurysm at the bend of the elbow; and says:—"I have treated but one such case in the person of an old ship's-carpenter. While at work, as usual, he felt something snap in his arm, a pulsating tumour was soon after noticed, and it had attained, during four months, fully the size of a hen's egg, and was evidently, in part, made up of solid matter. The brachial artery was tied, and every thing went on favourably." (p. 181.)]

1462. If the aneurysm be seated in the trunk of the brachial artery, at the bend of the arm, or in the ulnar (1), radial (2), or interosseal artery near the bend, it is sufficient to tie the brachial artery (*b*). But if it be situated in the middle of the fore-arm, in the region of the wrist, it is necessary to tie the artery near the aneurysmal sac, because the free anastomosis on the back of the hand, is sufficient to support the aneurysm by the reflux of the blood (*c*).

The free anastomosis of the arteries of the arm always renders it advisable to undertake tying the artery near the sac, because in many cases the regurgitation of the blood continues the growth of the sac, and causes its bursting (*par.* 1423.) In an aneurysm originating from wound of the artery, in the middle of the arm, when the sac does not extend far upwards, the opening of the sac is to be effected according to Hunter's first plan.

[(1) Astley Cooper had seen "only one case of aneurism of the ulnar artery from disease; it was seated where the artery dips under the *pronator radii teres* and flexor muscles of the hand." The artery was tied above the swelling with great difficulty, and "the patient died from the constitutional irritation resulting from this operation." (p. 81.)

(2) Liston says he has "secured the radial and ulnar arteries in all parts of their course for small aneurysms." (p. 187.) In the College Museum there is a preparation of aneurysm of the radial artery an inch above the origin of the superficial volar branch. Astley Cooper mentions a case in which William Cooper, formerly Surgeon at Guy's Hospital, "in performing this operation, (tying the radial artery,) found the upper portion of the radial artery obliterated, and that the aneurism was supported by regurgitation from the hand, from the free anastomosis with the ulnar artery." (p. 81.)]

1463. In aneurysm upon the back or front of the hand, tying one or other of the large arteries of the fore-arm does not, on account of the extensive communications which the ulnar and radial arteries have with each other in the hand, prevent the blood flowing back with sufficient power to keep up the aneurysm. If in this case pressure be insufficient for curing the aneurysm, the sac must be opened, and the artery tied above and below; and if this be not possible, one of the principal arteries of the fore-arm must be tied, the sac opened, and the bleeding arrested by pressure. The same rules must be followed in wounds of the arteries of the fore-arm and hand (*d*).

1464. The brachial artery may be tied in any part of its course, from the arm-pit to the bend of the elbow. Its tying, therefore, must be con-

---

(*d*) Scarpa, above cited, p. 407.

sidered, *first*, at the end of the axillary artery, where it passes beneath the lower edge of the great pectoral muscle; *second*, in the middle of the upper arm; and *third*, at the elbow-joint.

1465. If the artery be to be *tied in the arm-pit*, the arm must be separated from the trunk, and the fingers carried along the inner edge of *m. biceps* into the arm-pit, for the purpose of ascertaining the course of the muscle, and the position of the artery. A cut is then to be made along the inner edge of the *m. biceps*, of two inches in length, which is to extend upwards to the middle of the neck of the upper arm-bone. The skin first and then the *aponeurosis* is to be divided, with a careful cut; or the latter is first raised with the forceps, and cut into with the bistoury held flat, so as to admit a director, upon which it is to be divided. The edges of the wound are now to be separated with blunt hooks from each other, when the inner edge of the *m. coraco-brachialis* and *biceps*, together with the median nerve, are now seen, and behind the latter lies the artery. The nerve is drawn carefully inwards, and the artery which is between it and the edge of the just-mentioned muscles isolated, and the needle carried carefully around it, so as not to include the internal cutaneous nerve.

If the operator keep on the inner edges of the *m. biceps* and *coraco-brachialis*, in the manner recommended, and draw the median nerve inwards, there is no danger of erring, which may easily be done if he keep somewhat more inwards, where the radial or ulnar nerve are met with; and if one of these be mistaken for the median, the artery will be sought in vain. The following is the relative position of the artery:—The artery is separated from the edge of the *m. biceps* and *coraco-brachialis* only by the median nerve; on its inner side is the internal cutaneous nerve, and these two nerves at once cover the front of the artery. Near the cutaneous nerve lies the vein, which frequently forms two or three branches, and these render the isolation of the artery difficult. Still further inwards lie the radial and ulnar nerves.

1466. In order to tie the brachial artery *in the middle of the upper arm*, a cut, two and a half inches long, is made through the skin, along the inner edge of the *m. biceps*. The aponeurotic expansion is then to be divided, and the artery is found on the inner edge of the just-named muscle covered with the median nerve, between its two accompanying veins. The edge of the *m. biceps* is to be taken hold of, and the median nerve drawn somewhat inwards, between which and the edge of the muscle the artery appears, and is easily isolated with the handle of a knife; the ligature is to be carried round it with DESCHAMPS' needle.

The brachial artery frequently divides high up. If the ulnar artery be given off high up, it is always observed to penetrate the *fascia* of the upper arm, and take a superficial course. If the radial originate high up, it for the most part accompanies the ulnar artery to the elbow-joint, and then separates from it (*a*). TIEDEMANN (*b*), who has very often noticed the high division of the brachial artery in the corpse, found in such cases the radial artery nearly always very superficial at the elbow-joint, immediately under the aponeurotic expansion, from the *aponeurosis* of the *m. biceps;* on which account it is very easily wounded, but can also be as easily tied. The ulnar artery lies beneath this *aponeurosis* of the *m. biceps*. If, on laying bare the brachial artery, two arteries are found, they must be alternately compressed, in order to ascertain whether the pulsation in the aneurysm be stopped, for the purpose of tying that one in which it is seated.

1467. To tie the brachial artery *at the bend of the arm*, a cut two inches long is to be made through the skin on the extended arm, in the direction of a line imagined to be drawn from the middle, between the

---

(*a*) HODGSON, above cited, p. 391.

(*b*) WALTHER, above cited, p. 63. Tabulæ Arteriarum, pl. xiv. xv.

two condyles of the upper arm-bone, obliquely inwards and upwards towards the inner edge of the *m. biceps.* The veins lying beneath the skin are to be avoided, the superficial *aponeurosis* of the *m. biceps* is to be opened without or with a director introduced, and the artery isolated, for which purpose the fore-arm should be somewhat bent.

The median nerve here lies upon the inside of the artery three or four lines distant from it; the median basilic vein lies sometimes upon, sometimes at the side of, and frequently beneath the artery; and farther outward is the median cephalic vein.

1468. To *lay bare the radial artery in the upper third of the fore-arm,* a cut should be made, about two inches long, through the skin, a little below the insertion of the tendon of the *m. biceps,* in the oblique direction of the ulnar edge of the *m. supinator longus.* The *aponeurosis* of the fore-arm is to be divided in the same direction, and the edge of the just-mentioned muscle inclined somewhat outwards, when the artery appears in the interspace between it and the *m. flexor carpi radialis.* A branch of the musculo-cutaneous nerve lies upon the outer side of the artery, which is accompanied by one or two veins.

In *laying bare the ulnar artery in the upper third of the fore-arm,* a cut two inches and a half long is to be made between the radial edge of the *m. flexor carpi ulnaris,* and the *m. flexor digitorum sublimis,* through the skin and *aponeurosis* of the fore-arm. The artery lies rather under the edge of the *m. flexor digitorum sublimis,* accompanied by a vein, and on its outer side by the ulnar nerve.

In *the lower part of the fore-arm,* where these arteries are quite superficial, they are very easily laid bare. With the radial artery the cut falls on the radial side of the tendon of the *m. flexor carpi radialis;* with the ulnar artery between the tendons of the *m. flexor carpi ulnaris* and *flexor sublimis digitorum.*

If the *ulnar artery be tied in the region of the wrist,* a cut an inch and a half long, and three or four lines to the outside of the pisiform bone, should be made through the skin and fatty cellular tissue, which often fills up the whole wound, and, in such case, must be in part removed. The ulnar nerve is now found opposite the pisiform bone, and to its outer side the ulnar artery, accompanied by two veins. The artery should be isolated, and the ligature applied above the origin of its hinder branch which anastomoses with the deep palmar arch.

To *tie the end of the radial artery,* the hand must be brought prone, and bent somewhat towards the fore-arm. A cut is to be made from the outside of the styloid process of the spoke-bone, to the upper part of the interspace separating the first and second metacarpal bones. After cutting through the skin, the veins coming into view are to be drawn outwards or inwards, and the delicate branches of nerves which cross the wound divided. The position of the tendons of the *m. extensor longus* and *brevis pollicis* is now to be ascertained, and between them, and towards the most depending part of the *carpus,* a kind of soft and thick *aponeurosis,* which covers this part, is to be divided. Beneath it are some little masses of fat, which, if in the way, are to be removed, and then upon the carpal bones a thin aponeurotic layer is seen, which allows the artery, with its accompanying veins, to show through. This layer is then divided upon the director, and the artery easily isolated (*a*).

(*a*) Manec, above cited, pl. vii. viii.

1469. The supply of blood to the arm, after tying the brachial artery, is effected by the branches of the *arteria profunda humeri*, and the anastomoses of the recurrent radial, ulnar, and interosseal arteries. If the brachial be tied above the origin of the *arteria profunda*, the blood flows through the ramifications of the circumflex humeral and subscapular arteries, into the ascending branches of the *arteria profunda*, and the recurrent radial and ulnar arteries.

[**White**, of Manchester (*a*), has given a beautiful engraving of the circulating branches fourteen years after the brachial artery had been tied just above the bend of the elbow, for a wound in bleeding.

In the Museum at St. Thomas's Hospital are two beautiful preparations of the anastomotic branches enlarged after the brachial artery had been tied. In the one a long portion of the artery had been obliterated, and sets of vessels are descending on either side from above the obliteration, to be received into others which ascend in similar manner from below it. In the other the obliteration is less extensive, and a single curved artery about as big as a crow-quill passes from the upper to the lower open part of the artery.—J. F. S.]

IV.—OF ANEURYSM OF THE EXTERNAL AND INTERNAL ILIAC ARTERY.

1470. **Astley Cooper** (*b*), in an aneurysm which extended four inches above and as many below **Poupart**'s ligament, and had burst, undertook to *tie the abdominal aorta*. For this purpose he made a cut into the white line three inches in length, in the middle of which was the navel, which, by a curve in the wound, was placed on its left side, and then a small opening made into the *peritonæum*, which was lengthened with a button-ended bistoury to the extent of the external wound. He then passed his finger between the intestines, down to the spine, scratched with his nail through the *peritonæum* on the left side, carried his finger gradually between the spine and *aorta*, and then passed a single ligature with a blunt aneurysmal needle around it. The ligature was carefully tied without including intestine, and the wound brought together with the quill suture and sticking plaster. The patient died forty hours after the operation; sensation and warmth had, however, returned on the thigh of the healthy side, but that of the diseased side was cold and bluish.

James (*c*), on account of an aneurysm of the external iliac artery, first tied the femoral, according to **Desault**'s and **Brasdor**'s proposal; and the aneurysm at first diminished a little, but soon increased. He then proceeded to tie the abdominal *aorta* as **Astley Cooper** had done, only that he began his cut in the white line an inch above, and terminated it two inches below the navel. The patient died the same evening.

Murray (*d*) tied the *aorta* on account of a very extensive iliac aneurysm. He made a cut through the skin and muscles, beginning from the jutting extremity of the tenth rib, and continuing it about six inches down, curving in a direction backwards to an inch from the upper front spine of the hip-bone. He divided the transverse *fascia* on a director, separated with his hand, carried in flat, the *peritonæum* from the sheath of the *m. iliacus internus* and *psoas*, and easily reached the *aorta*. Passing the finger between the spine and *aorta* was more difficult, as also was the separation of the nervous *plexus* and the sheath of the *aorta*, which he

---

(*a*) Cases in Surgery, p. 139. London, 1770. 8vo.

(*b*) His and **Travers**' Surgical Essays, vol. i. pt. i. p. 393.

(*c*) Medico-Chirurgical Trans., vol. xvi. p. 1.

(*d*) London Medical Gazette, vol. xiv. p. 68, 1834.

effected partly with his nail, and partly with an elevator. Passing the aneurysmal needle was also very difficult. Drawing the ligature together did not excite any pain. The patient lived twenty-three hours after the operation.

It may be more convenient, as recommended by Astley Cooper, in tying the abdominal *aorta*, to make the cut about an inch distant from the epigastric artery, outwards, and running parallel to it, and to proceed as in tying the internal iliac artery.

According to Guthrie's recent views, it is in no case necessary to tie the *aorta*, because in an aneurysm of the external or internal iliac, the common iliac on the diseased side can always be got at, and if not there, yet on the healthy side, for the purpose of carrying a ligature around it.

[The *aorta* was also tied by C. D. Monteiro (*a*) at Rio Janeiro, *Aug.* 5, 1842, for an aneurysm of the femoral artery, close to the groin, which on examination turned out to be spurious, by the vessel having burst and formed a large swelling, occupying a great portion of the right under part of the belly. The incision was made on the left side, from the tip of the last false rib to the upper front iliac spine, through the abdominal walls, avoiding the *peritonæum*. The fingers were then carried down to the *aorta*, and a ligature with great difficulty passed around it by means of a ligature-needle. But little blood was lost. As soon as the ligature was tied, the aneurysm sunk down, but the artery swelled up (?), and for some time remained as a thick large knot. The case went on well till the *eighth* day; at three, P.M., arterial blood escaped through the dressings; it did not, however, affect the pulse, but patient's countenance was sunken and hollow. The bleeding continued, and on the *tenth* day, at 10 A.M., he died. The ligature had been placed two lines above the bifurcation of the *aorta*; a small opening was found on the left side of the vessel, immediately above the ligature.]

1471. If an aneurysm be situated on the external or internal iliac artery, or if it have extended so far upwards that there is not sufficient space between the aneurysm and the origin of these arteries to apply a ligature, tying the common iliac artery is indicated. Gibson (*b*) tied this artery for a wound; Mott (*c*) on account of an aneurysm of the internal iliac artery, Crampton (*d*) and Salamon (*e*) on account of a large external iliac aneurysm; Liston for secondary hæmorrhage; Guthrie for a presumed aneurysm of the gluteal artery; also Syme, Deguise, and Peace (*f*); but Mott's, Salamon's, Deguise's, and Peace's operations alone were successful.

1472. In order to *tie the common iliac artery*, an imaginary line must be drawn from the upper front spine of the hip-bone directly towards the white line: two and a half inches above this line, and two lines from the outer edge of the *m. rectus abdominis*, a cut should be begun, carried obliquely downwards and outwards, and terminated an inch and a half below the line, so that it has a length of from four to five inches. In this direction, the skin, the *fascia* of the external oblique muscle, the muscle itself, and then the *fascia* of the internal oblique muscle, are cut through; the transverse muscle with its *aponeurosis* is then divided with some careful strokes of the knife, or a director is introduced, and they are divided upon it. Any spouting vessel must be tied; the edges of the wound drawn asunder with blunt hooks by an assistant, and with the finger passed down into the wound, or with the handle of the knife, the cellular connexion of the *peritonæum* with the surrounding external parts must be divided. The patient's trunk is then to be inclined towards the healthy side, so that the intestines may drop away from the wound, and

---

(*a*) From a letter of Lallement's; in Schmidt's Jahrbücher der in und ausländischen gesammten Medecin. Jahrgang, 1843. Leipz.

(*b*) American Medic. and Surg. Recorder, 1820, vol. iii. p. 185.

(*c*) American Journal of Medical Sciences, vol. i. p. 156, 1827.

(*d*) London Medical and Surgical Journal, vol. v. p. 382.

(*e*) Froriep's Notizen, vol. iv. No. 3, 1837.

(*f*) Dublin Journal of Medical Science, vol. xxiii. p. 214, 1843, extracted from the Philadelphia Medical Examiner.

the division of the outer and under parts be facilitated. If there be not any diseased thickening, the separation is easy; but if there be, the bistoury must be used with the greatest care. The *peritonæum* with the *ureter* is now to be borne upwards, and being kept in that position with a spatula, by an assistant, the finger is to be carried down to the artery, which lies in a position corresponding with the cut. Below the artery and a little inwards, the accompanying vein lies; and at the lower angle of the wound pass branches of the ilio-lumbar artery and veins. The sheath of the artery must be torn with the nail of the forefinger, or with the handle of the scalpel, according as it is thinner or thicker; the artery is then isolated, and the needle carried round it, whilst the vein is pressed inwards (*a*).

MOTT made a cut, five inches long, beginning immediately above the external abdominal ring, and continued in a semi-lunar direction half an inch above POUPART'S ligament, to a little above the front spine of the hip-bone; he then divided the external and internal oblique and transverse muscles, and separated the *peritonæum* from its cellular connexions.

CRAMPTON carried a cut, seven inches long, from the seventh rib, downwards and forwards, to the front spine of the hip-bone, in a semicircular form, with its concavity towards the navel, cut through the three abdominal muscles, and separated the *peritonæum.*

According to ANDERSON (*b*), the cut should be commenced from the upper and front spine of the hip-bone, half an inch above POUPART'S ligament, parallel with it, continued towards the share-bone, and curved somewhat upwards, so that it is four inches long; cutting through the three abdominal muscles, and so on.

SALAMON made a cut about an inch from the upper front spine of the hip-bone, proceeding at similar height from it, and in parallel direction to the epigastric artery, terminating about a finger's breadth below the last false rib, and from four to four and a half inches long. The division of the abdominal muscles and transversal *fascia*, and so on.

1473. If an aneurysm be situated on a branch of the internal iliac artery, to wit, on the ischiatic or gluteal artery, tying the internal iliac is indicated, as the practice followed by J. BELL (*c*) in a case of ischiatic aneurysm arising from injury, viz., opening the sac and tying the artery above and below the wound is extremely dangerous, and only in few cases can be permissible. W. STEVENS (*d*) tied the internal iliac artery for an aneurysm above the ischiatic notch; J. ATKINSON (*e*) on account of a gluteal aneurysm, so also WHITE (*f*); MOTT (*g*), for a gluteal or ischiatic aneurysm. ATKINSON'S and MOTT'S cases were unfortunate, but the other two had the happiest result (1).

[(1) The internal iliac artery has also been tied successfully by a Russian army-Surgeon (*h*); also by my friend THOMAS, of Barbadoes, but the patient died, and the preparation is in Guy's Museum (*i*).]

1474. To *tie the internal iliac artery*, a cut of five inches in length is to be made through the skin and three muscles, upon the under and outer side of the belly, parallel to the course of the epigastric artery, and an inch to its outer side. The exposed *peritonæum* is to be separated with the finger from the *m. iliacus internus* and *psoas magnus*, and the finger carried down to the internal iliac artery, which should be detached by it from its connexions; and about half an inch below its origin a ligature is to be carried round it with an aneurysmal needle.

(*h*) AVERILL'S Operative Surgery, p. 79.
(*i*) Med.-Chir. Trans., vol. xvi. p. 230.

In this way **Stevens** proceeded, and this operation is most proper and safe. **White** made a semicircular cut seven inches long, beginning two inches from the navel, and continuing it nearly down to the external inguinal ring.

According to **Anderson** and **Bujalsky**, the cut should be begun a finger's breadth above the upper front spine of the hip-bone, or even higher, and half an inch distant from **Poupart's** ligament, but continued parallel to it for about three inches towards the share-bone. Cutting through the three abdominal muscles, separation of the *peritonæum* and retracting it together with the spermatic cord upwards.

[The following are the particulars of **Owen's** dissection (*a*) of **Stevens'** case. The woman died ten years after the internal iliac artery had been tied. The internal iliac artery had become impervious at the part where the ligature had been applied, and "the ilio-lumbar appears to have arisen just above this point, the obliteration in consequence had not extended to the origin of the external iliac. In the state of a ligamentous cord, the internal iliac descended towards the ischiatic notch for the space of an inch, and then suddenly resuming its natural diameter it again became pervious, and so continued for the extent of half an inch; the glutæal artery arising from the lower part of this space; a sacro-lateral vessel from about the middle; and the obturator artery from the upper part of it. The latter vessel was, however, entirely obliterated, but the sacro-lateral artery was pervious, of the size of a crow quill, and passed inwards to the second sacral *foramen*; whilst the glutæal artery, of its natural size, received close to its origin two vessels as large as the preceding, given off from the sacro-lateral artery, near the third and fourth sacral *foramina* of the left side. The anastomoses of the sacro-lateral arteries with each other and the sacro-median were large and tortuous. Immediately after the origin of the glutæal artery, the ischiatic, obliterated and cord-like, passed on to the lower part of the ischiatic notch; the sanatory processes set on foot by the application of the ligature being uninterrupted by the enfeebled current of blood passing from small canals to a large one. Many vessels met with in the course of the dissection of the *glutæus maximus* and *medius* were found to have received the injection. The glutæal artery was in a healthy condition, and of the natural size; but an elongated tumour, situated between the tuberosity of the *ischium* and the great *trochanter* indicated the true seat of the original disease. This tumour in length three inches and a half, and above two-thirds of an inch in breadth, was of the sciatic artery, and consisted of layers of condensed cellular membrane and the peculiar fibrous arterial coat. It contained a quantity of dark-coloured granular not lamellated coagulum, which, when removed, showed the internal surface of the sac to be somewhat irregular and raised in small patches by the deposition of soft matter. In some places it appeared to retain the smooth character of the arterial lining membrane. From the ischiatic notch to the tumour, the artery was completely obliterated, its texture altered and the remains of the cavity filled with indurated and partly calcareous matter. From the lower part of the tumour the sciatic artery was continued down the posterior part of the thigh of an uncommon size, nearly as large as the femoral artery in front; its calibre did not, however, correspond with the apparent magnitude, for its coats were thicker, by at least one-half than any artery of the same size with itself. It was obliterated for about the space of an inch below the sac, and became pervious after receiving an anastomosing vessel from the *arteria profunda*. A vessel ramifying between the *glutæus maximus* and *medius*, and distributing branches to these muscles, was connected to the commencement of the sac, from which it had probably arisen; it did not, however, open into the sac, but after becoming contracted near the point of attachment, it there gave off a small artery to the *quadratus femoris* and received its blood by anastomosing near the *crista ilii*, with a superficial branch of the glutæal artery. A smaller vessel was similarly attached to the lower part of the aneurysmal sac, but neither did it communicate with that cavity, for the blood which it received from branches ramifying in the neighbourhood was diverted from the sac by a small branch given off at the point of attachment." (p. 222-25.)]

1475. If *the gluteal artery is to be tied*, a cut three inches long should be made through the skin and cellular tissue, commencing at the upper hinder spine of the hip-bone, and carried in the direction of the fibres of the great gluteal muscle, towards the great *trochanter*. The fibres of the great and middle gluteal muscles are to be divided in the same direction, to the lower edge of the hip-bone and the artery found.

Carmichael (*b*) tied the gluteal artery, for spurious aneurysm, by a penknife wound

---

(*a*) Med.-Chir. Trans. vol. xvi.

(*b*) Dublin Journ., vol. iv. p. 231, 1833.

in the way just directed. From one to two pounds of coagulated blood were emptied out. The vessel could not be taken up with the tenaculum; but a ligature, with a large common needle, having been passed round it, was tied, and came away in six days. The boy was convalescent in sixteen days.

To *tie the ischiatic artery*, a cut two and a half inches long must be made through the skin and cellular tissue, commencing immediately below the under hind spine of the hip-bone, and continued along the fibres of the great gluteal muscle, towards the outside of the tuberosity of the haunch-bone, where it is connected with the rump-bone, and the artery is found lying on the ischio-sacral ligament (*a*).

1476. If *the common pudic artery is to be tied*, a cut of an inch or an inch and a half long should be made along the inside of the descending branch of the haunch-bone, through the skin, cellular tissue, *fascia* of the great gluteal muscle, and through the muscle itself. The edges of the wound are to be kept asunder with blunt hooks, by which a layer of fat is exposed, and beneath it lies the artery. This is to be divided, or partially removed till the *m. erector penis* be laid bare, on the inner side of which muscle lies the vessel, accompanied by two veins and a branch of the pudic nerve. The transverse perinæal artery also accompanies the pudic, running almost parallel with it. The artery is to be carefully isolated, and the needle carried round it, from within outwards (*b*).

[In the Museum of the Royal College of Surgeons there is an example of aneurysm of the pudic artery an inch in diameter, and nearly filled with clot. Whilst alive, the patient had a strongly pulsating tumour under the left great gluteal muscle; he was much out of health, and died. On *examination*, there was found beneath the hinder edge of the muscle a tumour, as large as a walnut, upon the ischiatic notch, and adhering to the ischiatic nerve as it left the *pelvis*. The artery was the internal pudic, and it was healthy above till it at once dilated into an aneurysm, below which it was obliterated, so that there was no outlet for the blood: the coats were strong like the coats of many encysted tumours.—J. F. S.]

V.—OF ANEURYSM OF THE FEMORAL AND POPLITEAL ARTERIES, AND THEIR BRANCHES.

1477. Abernethy (*c*) was the first who tied the external iliac artery in the groin for aneurysm. This case, although not successful, showed the possibility of the limb being sufficiently supplied with blood after obliteration of the artery.

[The first time Abernethy tied the external iliac artery was in the early part of the year 1796, on a patient in St. Bartholomew's Hospital who had popliteal aneurysm in one, and femoral aneurysm in the other leg. The femoral artery was tied for the cure of the former by Sir Charles Blicke with two ligatures, between which it was divided; the upper ligature came away on the tenth and the lower on the fifteenth day, and the cure was perfected. "About five weeks after this operation, the aneurism in the opposite thigh was almost ready to burst, the tumour having acquired a pyramidal form, and the skin covering the apex having yielded so much as to form a kind of process from the tumour. Indeed, the integuments at this part were so thin, that we every hour expected them to give way. The aneurism was situated so high, as to make it probable that the disease extended above the place where the *arteria profunda* is sent off," and prevented pressure being made upon the artery, except at the place for incision; but even here it did not stop the pulsation, and troublesome bleeding occurred during the operation. A small opening made in the *fascia* of the thigh admitted the finger, upon which it was divided up to Poupart's ligament, and down to the sac. The pulsation directed the finger and thumb to the artery, which was tied with two ligatures,

(*c*) On Aneurysms; in the Medical and Physical Journal, vol. vii. p. 97, 1802, and in his Surgical Works, vol. i. p. 254. The first case here mentioned is cited from the latter, and the second from the former work.—J. F. S.

the upper half an inch from the *os pubis*, and the lower the same distance from the *arteria profunda*, but the artery was not divided between them. "The tumour diminished greatly after the operation, and the blood contained in it became coagulated, which it did not appear to have been before the operation." * * * Every thing went off well till the fifteenth day, when the upper ligature separated, and the blood gushed in a full stream from the open extremity of the vessel. The bleeding was stopped by pressure. The stream of blood which flowed upon any remission or wrong application of the pressure was so large that we did not dare to remove the patient even from the bed on which he lay. Mr. RAMSDEN undertook, in this situation, to prevent the further escape of blood from the vessel, whilst I proceeded to tie the artery above POUPART's ligament. Accordingly, I first made an incision, about three inches in length, through the integuments of the *abdomen*, in the direction of the artery, and thus laid bare the *aponeurosis* of the external oblique muscle, which I next divided from its connexion with POUPART's ligament, in the direction of the external wound, for the extent of about two inches. The margin of the internal oblique and *transversalis* muscles being thus exposed, I introduced my finger beneath them for the protection of the *peritonæum*, and then divided them. Next with my hand I pushed the *peritonæum* and its contents upwards and inwards, and took hold of the external iliac artery with my finger and thumb, so that I was enabled to command the flow of blood from the wound. It now only remained that I should pass a ligature round the artery and tie it; but this required caution, on account of the contiguity of the vein to the artery. I could not see the vessels, but I made a separation between them with my fingers. Having, however, only a common needle with which to pass the ligature, I several times withdrew the point from apprehension of wounding the vein. After having tied the artery about an inch and a half above POUPART's ligament, I divided that part, and thus laid bare ithe new and the former wound into one. * * * No adhesion took place between the divided parts; the edges of the wound were open and sloughy. * * * Still no greater mischief appeared till the fifth day after the operation, when a hæmorrhage of arterial blood took place in such quantity that there was no doubt but that it arose from the principal artery, though the ligature with which it was tied still remained firm." No further attempt at tying the vessel higher up was made, but compresses were fixed with a bandage, and continued for three days, but there was still occasional, though not profuse bleeding. "In the course of the eighth day after the last operation he died." On *examination*, it was found, that, "for nearly two inches above the part which was tied, the lymphatic glands covering the artery were considerably enlarged. The external surface of one of them next the wound had ulcerated, and the ulceration penetrated through the gland, and communicated with the artery. * * * The ulcerated opening from the artery, through the diseased gland, admitted the passage of a moderate-sized bougie." (p. 254–66.) ABERNETHY remarks:—"In this case I thought I disturbed the *peritonæum* too much, and tied the artery higher than was necessary." (p. 269.) This accordingly he avoided in his second operation on the 24th of October, 1801, and having divided the edges of the internal oblique and transversal muscles, "I now introduced," says he, "my finger beneath the bag of the *peritonæum*, and carried it upwards by the side of the *psoas* muscle, so as to touch the artery about two inches above POUPART's ligament. I took care to disturb the *peritonæum* as little as possible, detaching it to no greater extent than would serve to admit my two fingers to touch the vessel." (p. 99.) The artery was then tied with two ligatures and divided between. He went on tolerably till the fifth day when "the wound and contiguous parts looked remarkably well, but a bloody sanies was discharged which I felt unable to account for. On the sixth day the state of his health and limb continued as well, if not improving. The bloody discharge, however, had increased in quantity, insomuch that it ran through the coverings of the wound and soiled the bed; it had also become fœtid. * * * I could not believe that a healthy wound would secrete such a sanies, and I felt apprehensive lest the wound should spread from disease. Nothing, however, took place to confirm this idea. It seemed probable, also, that if the aneurysmal sac were not entire, some of the blood being exposed to the air, might tinge the discharge from the wound and grow putrid. I frequently pressed on the tumour, but could press no blood from the wound." On the ninth day he "appeared like a man advanced in typhus fever. * * * On examining the wound, with a view to discover the cause of this great and sudden alteration, and pressing on the tumour beneath POUPART's ligament, I forced out a great quantity of blood rendered fluid and highly fœtid by putrefaction." He continued slowly sinking, and died "on the twenty-third day after the operation. A few days before his death both ligatures came away with the dressings." On *examination*, it was found that "the *peritonæum* was separated from the loins, and from the posterior half of the left side of the *diaphragm*, by a considerable collection of blood which extended below to Poupart's ligament, and communicated under that ligament with the aneurysmal sac This opening was situated in the direction of that crevice which is found between the internal iliac and *psoas* muscle. The only rational explanation that can be given of the formation of this collection is, that the blood had burst its way from the aneurysmal sac in the vacancy between the muscles just mentioned, after which it would readily and extensively separate the *peritonæum* in the manner described. * * * The extremities of the external iliac artery, which had been divided in the operation, were united together by a fine newly-formed substance; the sides of each extremity were perfectly closed, and a small plug of coagulated blood was found in each. * * * It seems evident that, in the present instance, the operation was too long delayed. It would be desirable in future to perform the operation before an extensive diffusion of blood had taken place; indeed, could the adequateness of the collateral arteries for the supply of the limb be established, it would be proper to operate before the artery had burst." (p. 101–104.) Abernethy's third case operated on the 11th of October, 1806, on which the ligatures came away,—the lower on the fifth, and the upper on the fourteenth day,—succeeded, as did also his fourth on the 25th of February, 1809, in which the ligatures came away on the tenth day. Abernethy's case was not, however, the first successful one as on the 4th of October, 1806, Freer (*a*) tied the external iliac artery with a single ligature, which came away on the sixteenth day, just anticipated Abernethy's by five days. Within the year, Tomlinson of Birmingham also successfully tied the same vessel with a single ligature, which separated on the twenty-sixth day. Astley Cooper's first case, also successful, is most important of all, though not performed till the 22nd of June, 1808, as he had the opportunity on the patient's death, 18 years after, of examining the condition of the tied vessel and of the anastomosing arteries.

Both external iliac arteries have been taken up in the same subject at the interval of a week, in one instance by Tait (*b*), and in the other by Arendt (*c*), and did well.]

1478. Tying the *external iliac artery* is not merely indicated in aneurysms above the *arteria profunda femoris*, but also in those below the origin of that artery, which extend so close to Poupart's ligament, that there is no space for the operation between it and the aneurysm; which practice is certainly preferable to opening the sac, with compression of the femoral artery on the horizontal branch of the share-bone, in order to avoid the *arteria profunda*.

1479. The *external iliac artery is to be tied* in the following manner. The patient being placed on a couch with his buttocks somewhat raised, the operator stands on the side on which the operation is to be performed, and makes a cut through the skin and cellular tissue, commencing half an inch to the inside of the upper front spine of the hip-bone, and terminating at the middle of Poupart's ligament. The cut should be continued in the same direction, through the *aponeurosis* of the external oblique muscle, the muscular fibres of the internal oblique muscle, and with the greatest care through the thin *aponeurosis* of the transverse muscle, so as not to wound the *peritonæum*. The exposed *peritonæum* is to be separated with the finger at the lower angle of the wound, from its yielding connexion with the *m. iliacus internus*; and pressing it inwards, the external iliac artery is felt, accompanied on the inside by the vein, and on the outside by the crural nerve. It is then to be isolated with the finger or with the handle of the knife, and the ligature carried round it with Deschamps' needle; this last proceeding can, at least in the dead body, be facilitated by bending the thigh at the hip-joint.

The decisions as to the direction and size of the cut in this operation are very various. They may be arranged in three classes.

1. With a nearly *straight* cut.

Abernethy made a cut four inches long, commencing an inch and a half from the upper front spine of the hip-bone, nearer the white line, and carried it down in the

---

(*a*) Above cited, p. 80.

(*b*) Samuel Cooper's Surgical Dictionary, p. 157.

(*c*) Velpeau, Nouv. Elémens de Médecine Opèratoire, vol. i. p. 175

direction of the external iliac artery to half an inch above Poupart's ligament. He divided first the skin, then the *aponeurosis* of the external oblique abdominal muscle, and carried his finger under the lower edge of the internal oblique and transverse muscles, in order to protect the *peritonæum*, whilst he divided those muscles with a common or button-ended bistoury. The *peritonæum* was pressed back with the finger.

According to Charles Bell, the cut should be commenced at the outer pillar of the abdominal ring, carried outwards and upwards, and terminated half an inch above the upper front spine of the hip-bone, and two fingers' breadth to its inner side. The *aponeurosis* of the external oblique muscle is then to be divided from the ring upwards, upon a director, the lower edge of the internal oblique muscle raised, the spermatic cord drawn inwards and upwards, with a blunt hook, the cellular tissue put aside, and the artery isolated. But if there be not sufficient space to apply the ligature, the internal oblique muscle must be divided upwards and outwards.

Scarpa begins the cut half an inch under the upper front spine of the hip-bone, and an inch and a half from it nearer the white line, and carried down near to the crural arch. Division of the three abdominal muscles and separation of the *peritonæum*.

(2) With a *semilunar* cut.

Astley Cooper makes a semielliptical cut, beginning near the spine of the hip-bone and terminating a little above the inner edge of the outer abdominal ring. The *aponeurosis* of the external oblique is divided in the same direction. This flap being now a little raised, the course of the spermatic cord is seen, and if followed by the finger under the edge of the internal oblique muscle, the opening in the *fascia transversalis* (inner ring) is entered, and the finger touches the artery (4).

The practice of Lisfranc and Anderson agrees with this, but the latter makes the cut less curved and a little shorter, (not quite three inches,) separates the skin upwards and downwards, and dividing the *aponeurosis* of the external oblique muscle, terminates the cut a little before the external abdominal ring. The *aponeurosis* is then to be separated from the internal oblique muscle, with the handle of the knife: the spermatic cord now exposed, is to be raised, and its sheath lifted up and cut through with the knife or scissors. Through this aperture the little finger of the right hand is to be carried to the internal ring, and the artery being reached, is then to be separated from the iliac *fascia* and vein by the introduction of a silver aneurysmal needle, and tied.

Rust considers that the cut should be made in the same way, only three and a half inches long, through the three abdominal muscles and the epigastric artery, which must at once be tied.

(3) With an *oblique* incision.

Langenbeck, Delpech, and others, determine that the cut should be commenced two fingers' breadth from the upper front spine of the hip-bone, and continued across towards the *m. rectus* a finger's breadth from Poupart's ligament, so that the cut should be four fingers broad. The division of the three abdominal muscles and so on.

Wright and Post (*a*), in case of an aneurysm extending high up, made a cut four inches long, from the upper end of the swelling, to a point, between the navel and the upper front spine of the hip bone. The *peritonæum* much thickened by the pressure of the swelling needed cutting. Bujalsky also makes the incision in the same direction.

Compare Dietrich (*b*) on the preference and objections to these different operations.

[(4) Upon Cooper's mode of tying the external iliac Guthrie observes :—"It offers the advantage of greater space, which enables the Surgeon to see better what he is doing; but it does not so readily admit of the artery being tied high up, without an additional incision being made in a direction different from the first, which is after all a matter of no consequence, if it were found necessary to do it." (p. 375). He also mentions that he "has seen the epigastric artery divided in this operation.* * * If the Surgeon has unluckily divided it, either in this or in any other operation, all that he has to do is to enlarge the incision and tie both the divided ends; and I have no hesitation in saying it will not be of any consequence, either in this operation or in one for *hernia*. If a man has been so unfortunate as to have a wound in his *peritonæum* of a quarter or of half an inch in extent, two ligatures on the epigastric artery, and a slight increase on the extent of the external incisions, add little or nothing to the danger, which only takes place in reality when the wound is closed up, and the artery is allowed to bleed internally." (p. 376.) Dupuytren did not, however, find this to be exactly the case when he divided the epigastric artery in 1821; the bleeding was very copious, and though he stopped it by putting on two ligatures, the patient died in a few days of *peritonitis* (*c*).]

1480. If there be room *beneath* Poupart's *ligament to apply a ligature around the femoral artery*, a cut is to be made midway between the iliac

---

(*a*) American Med. and Phil. Register, vol. iv. p. 443.

(*b*) Above cited, p. 284.

(*c*) Averill's Operative Surgery, p. 73.

spine and pubic *symphysis*, beginning at the edge of POUPART's ligament, and continued somewhat obliquely from above downwards. The skin and underlying fat are to be divided, the glands separated, and the superficial layer of the *fascia lata* divided, where the artery is found in the canal formed by the two layers of that *fascia*, having the vein on the inner, and the nerves on the outer side.

The femoral artery commonly gives off the *arteria profunda* an inch and a half, or two inches below POUPART's ligament; but it frequently arises before the femoral artery has passed under POUPART's ligament. For this reason the direction to begin the cut an inch below POUPART's ligament is improper, because here, manifestly, although the cut may be several inches long, yet the space is too confined for isolating the artery.

TEXTOR and ROBERT FRORIEP make a cut two and a half inches long, half an inch below POUPART's ligament, and parallel to its lower edge, so that it corresponds to the middle of the femoral ring. In the same direction the cellular tissue and *fascia* are to be divided upon a director, in doing which the director is only to be introduced a short distance, and the division to extend three lines from the two edges of the wound.

1481. The vessels by which the circulation is kept up, after tying the external iliac artery, are the anastomoses, between the gluteal, ischiatic, internal pudic, and obturator, with the circumflex arteries, which arise from the deep artery, from the external pudic, epigastric, and circumflex iliac arteries. If the obturator arise from the epigastric, a large quantity of blood passes through its anastomosis with the internal pudic and ischiatic, and the branches of the circumflex artery of the thigh. The epigastric and circumflex iliac artery also convey blood by their anastomoses with the internal mammary, with the intercostal, lumbar, and sacral arteries. If, therefore, the aneurysm be below the epigastric artery, there may be, after the obliteration of the external iliac artery, a flow of blood above the seat of aneurysm into the artery, but no enlargement of the aneurysm from it is to be feared (1).

There are a considerable number of cases in which the external iliac artery has been tied. Fifteen out of twenty-two have been (according to HODGSON) cured; a very good proportion, if it be remembered that many of the patients had been already much weakened by previous bleeding from the sac (*a*).

[MOTT (*b*) tied the external iliac artery fourteen days after tying the femoral of he other limb; in both on account of aneurysm. The case did well.

The following are the principal points in the dissections of three of the cases in which ASTLEY COOPER tied the external iliac artery.

In the case (*c*), which died ten weeks and six days after the operation, "it was found that the femoral, tibial, and fibular arteries were still open, and that the blood was conveyed into the femoral artery by the following anastomoses. The internal pudendal artery formed several large branches upon the side of the bulb of the *penis*, and these branches freely communicating with the external pudendal artery had determined the blood into that artery, and by this channel into the femoral; the lateral sacral artery also sent a branch on the *iliacus internus* muscle, into the femoral artery, and the ilio-lumbar artery freely communicated with the *circumflexa ilii;* so that, by these three routes, the blood found direct ingress to the femoral artery. Numerous branches of arteries also passed from the lateral sacral to the obturator and epigastric arteries, the obturator in this case having its origin from the epigastric. Besides these arteries, a free communication existed between the *arteria profunda* and circumflex arteries, with the branches of the internal iliac; first, the gluteal artery sent a branch under the *glutæus medius* muscle to the external circumflex artery; secondly, the ischiatic artery gave two sets of branches of communication, one upon the *glutæus maximus* muscle to the *arteria profunda*, and another upon the sciatic nerve to the internal circumflex artery; the internal pudendal artery also sent a branch of communication to the internal circumflex; lastly, the obturator freely communicated with the internal circumflex." (pp. 428, 29.)

In COOPER's second case (*d*), "examined, at three years after tying the external iliac artery," the external iliac and the femoral arteries were obliterated, excepting about an inch of the femoral artery, just below POUPART's ligament, which still remained open,

---

(*a*) HODGSON, above cited, p. 416.

(*b*) American Journal of Medical Sciences, vol. i. p. 483.

(*c*) Med.-Chir. Trans., vol. iv. 1813.

(*d*) Ibid.

and continued to convey a portion of the blood; but, below this part, it had become simply a ligamentous cord. The internal iliac artery sent first a very large artery of communication to the epigastric and obturator artery, so that the epigastric was supplied with blood from the internal iliac; secondly, the internal iliac sent an artery of communication upon the sciatic nerve, to the internal circumflex artery. The gluteal artery gave a large branch to the origin of the *profunda;* lastly, the internal pudendal artery largely anastomosed with the obturator; the obturator, therefore, sprang in this case from two new sources, viz. from the internal iliac, and from the internal pudendal artery, and the obturator thus formed sent two branches of communication to the internal circumflex artery. The *arteria profunda* was in this case supplied from two sources directly from the gluteal, and more indirectly from the internal circumflex, by the obturator and ischiatic arteries. The external iliac artery was obliterated to the origin of the internal iliac, as other arteries usually are when ligatures are made upon them to the first large anastomosing vessel. The principal agents then of the new circulation are the gluteal artery with the external circumflex, the obturator artery with the internal circumflex, and the ischiatic with the *arteria profunda,* and the obturator artery is supplied with blood principally by the internal pudendal when the obturator arises from the epigastric artery." (p. 429–31.) Both preparations are in St. Thomas's Museum.

In COOPER's third case (*a*), eighteen years after the operation, "the external iliac artery was pervious to the extent of rather more than an inch from the bifurcation of the common iliac, but had become somewhat diminished in size, and altered in shape. No branches were given off from this portion of the vessel, which, when filled with injection, presented a conical form, tapering downward to a mere point, and terminating in a rounded cord which constituted the remaining part, or the obliterated portion of the artery, and was continued down to the spot where the operation had been performed. The ligature had probably been applied just above the origin of the circumflex and epigastric branches, although no evidence remained to indicate the precise spot. Just above POUPART's ligament the iliac artery became suddenly restored, (apparently by the influx of blood from the branches mentioned above,) and assumed about half its natural size. The obliterated vessel presented the appearance of a continuous unbroken cord, from the cessation of the iliac above to its restoration below. * * * The vessel having regained about half its natural size, passed into the thigh and was continued without receiving any accession from collateral vessels, until it reached the origin of the *profunda;* from which branch the trunk appeared to derive a large quantity of blood, sufficient to restore it to the ordinary extent of calibre which the femoral possesses in a stout muscular limb; the remaining portion of the femoral artery below the *profunda* presented nothing unusual in its appearance, and bore no indication of having received any further influx of blood through collateral branches. Just above the origin of the *profunda,* the femoral artery had become distorted, and irregular in shape, and was rendered somewhat obscure by its connexion with what appeared to be the remains of the aneurismal sac adhering to the anterior surface of the vessel and gluing it to the adjacent muscles and *fascia.* There can be but little doubt that the original opening of communication between the sac and the femoral trunk had existed at this spot, viz. just above the *profunda* branch; but it would seem equally apparent that, as the aneurismal tumour became obliterated in the progress of the cure after the operation, the opening into the vessel also became closed, while the integrity of the arterial trunk, above and below the sac, was maintained continuous and entire. The collateral circulation had, in this instance been established by the junction of the ilio-lumbar, obturator, gluteal and ischiatic, branches from the internal iliac, with the circumflex and epigastric of the external iliac and the *profunda* of the femoral. They consisted of three sets of communicating vessels which descended respectively over the fore part, the internal side, and the posterior surface of the hip-joint, and may be described as forming a circular *plexus* around the articulation, ramifying among the muscles of that region. * * * The ilio-lumbar, gluteal, and ischiatic arteries are enormously dilated. The internal pudic is also of large size, but it does not appear to furnish any direct communication with the femoral." (p. 48–50.) This preparation is in the Museum of Guy's Hospital.]

1482. If the aneurysm be situated in the lower third of the thigh, or at the knee-joint, it is best to *tie the femoral artery* in the following manner. The pulse of the artery should be followed from the groin downwards, and where it is only indistinctly felt is to be the end of a cut, which begins about two and a half inches below POUPART's ligament, and descends on

---

(*a*) Guy's Hospital Reports, vol. i. 1836.

the inner edge of the *m. sartorius*, in the triangular space formed by the *m. adductor secundus* and *vastus internus.* The skin and *fascia lata* being divided, and the edge of the *m. sartorius* drawn somewhat outwards, the artery is found enclosed in its cellular sheath, with the femoral vein under it, and the branches of the crural nerve on its outer side. When the artery is properly isolated, the ligature is to be carried round it with the aneurysmal needle (*a*).

JOHN HUNTER tied the femoral artery in the lower half of the thigh; dividing the skin and *fascia lata* on the inside of the *m. sartorius* to the extent of three inches, he laid bare the edge of this muscle, isolated the artery lying beneath, and tied it near the place where it passes through the tendon of the *m. adductor* (*b*). If the artery be tied in the upper half of the thigh, he thinks it best done at the inner edge of the *m. sartorius*; and if in the lower half, at the outer edge (*c*), which, after having been laid bare by a cut three inches long, is to be drawn somewhat inwards, where the artery is covered with a slip of *aponeurosis*, passing from the *m. adductor* to the *m. vastus internus;* this must be cut through, and the artery isolated in the way already mentioned.

1483. If an aneurysm be in the ham or on the upper part of the arteries of the leg, there may be sufficient space for tying the artery in the ham; but on account of the depth of the vessel, of the difficulty of its isolation, its nearness to the joint, and so on, this operation is to be considered as by far more dangerous and less safe than that of tying the femoral artery. In aneurysms, tying the femoral artery is to be unconditionally preferred, and only in cases of wound of the popliteal artery is its tying indicated, in which sufficient enlargement of the wound is usually necessary. As for the rest, the popliteal artery has been tied in three different parts, at the *middle*, *upper*, and *lower* part of the ham.

1484. If the artery is to be laid bare *in the middle of the ham*, the patient having been placed on his belly, and the thigh perfectly extended, a cut, three inches long, is to be made a little to the inner side of the mesial line of the ham, through the skin and *aponeurosis*, taking care to avoid the *vena saphena;* the edges of the wound being then separated, the Surgeon penetrates deeper with careful cuts, and with the handle of the knife through the cellular tissue, often much loaded with fat, down to the popliteal nerve, vein, or artery itself. The nerve lies on the outer side, and between it and the artery is the vein, which covers the outside of the artery. The nerve should be drawn aside, and the artery separated with the greatest care from the vein, so as to wound neither the articular veins nor arteries. When the needle is to be carried round the artery, the leg must be somewhat bent.

If the artery be tied *in the upper part of the ham*, a cut is to be made somewhat on the inside of the base of the triangular space formed on the inside by the *m. semi-tendinosus* and *semi-membranosus*, and on the outside by the *m. biceps femoris*, to the top of this triangle, the skin and *aponeurosis* are divided, and the rest of the operation performed as in the former case.

In tying the popliteal artery *at the lower part of the ham*, the cut is to be made somewhat on the inside of the mesial line, and some lines below the knee-joint, from three to four inches long, above the hind part of the leg, through the skin, cellular tissue, and *aponeurosis;* the interspace between the two heads of the *m. gastrocnemius* then appearing, these are to be separated, and the trunk of the vessel and the sural branches come into

(*c*) CAILLOT, above cited, p. 72.—WEGEHAUSEN, in RUST's Magazin für die gesammte Heilkunde, vol. ii. p. 408.

view with the veins and posterior cutaneous nerves of the leg. These parts are to be drawn aside by an assistant, and the cellular tissue being divided with the handle of the knife, the popliteal artery is found on the inner side, the vein in the middle, and the nerve on the outside. If the cut be somewhat lengthened in this proceeding, the posterior tibial artery may be tied at its upper part (*a*).

Jobert (*b*) ties the artery in the internal epicondyloid pit, viz., in the triangular depression bounded within by the *m. sartorius, gracilis, semi-tendinosus* and *semi-membranosus.* The knee is to be half bent, and a cut made on the outer edge of these muscles, two inches long, through the skin to the fatty tissue. The skin is to be then drawn outwards, and a second cut across the former made, but without wounding the skin, by which the tendinous expansion of the *m. adductor magnus* is divided. The forefinger is to be passed beneath the tendinous expansion, and a button-ended bistoury introduced upon it, to cut through the superficial layer of the *aponeurosis* which covers the artery. The pulsation of the artery is then felt, and in some thin persons may even be seen. The fatty tissue is to be penetrated with a director, which is carried with the greatest care between the artery and vein.

1485. If the aneurysm be situated at the commencement of the tibial artery, the femoral must be tied in the way mentioned (1). But if it be lower on the tibial artery, the inflow of blood, after tying the femoral artery, is sufficient, in large aneurysms of the foot, to keep up the disease, and it is therefore necessary to tie the affected artery in the neighbourhood of the aneurysmal sac (2).

[(1) The following case of aneurysm of the posterior tibial artery is a good example of the practice recommended:—

Case.—M. H., aged 38 years, was admitted,

Sept. 13, 1832, with a pulsating tumour at the back of the upper part of the right leg. He had fallen down stairs a twelvemonth since upon a brush, and at the same time twisted his leg, which laid him up with great pain and swelling for ten days, but after that time he seemed to get well, excepting that he had a little continual pain and always a throbbing behind and below the head of the *fibula.* Six months since, after having walked a considerable distance, his leg began to swell and be so painful as to compel him to keep at rest. There is now distinct pulsation below the head of the fibula and at an opposite point on the inside of the leg beneath the gastrocnemial muscles. The posterior tibial artery does not pulsate at the ankle; and the anterior tibial beats but feebly. The girth of the affected leg at this part is nearly sixteen inches, whilst in the other it is only thirteen and a half inches. The temperature of the limb is diminished; and he has numbness and pricking of the whole limb below the tumour, more particularly affecting the foot. Pressure of the femoral artery at the groin, or on the sides of the swelling, diminishes it half an inch, but it fills immediately, when the pressure is withdrawn.

Sept. 21. My colleague Green tied the femoral artery at the usual place in the middle of the thigh. The pulsation ceased when the ligature was tightened.

Oct. 2. Has been going on well; the limb about an inch smaller, but more yielding: the pricking and numbness of the foot have ceased.

Oct. 30. The ligature came away. After which the wound soon healed; but at two months' end the size of the limb had only diminished an inch.

Astley Cooper mentions a case of "anterior tibial aneurism a little below the head of the fibula, for which the femoral artery was tied; the pulsation ceased in the aneurism, and the swelling for a time subsided. The case did not ultimately recover, for a slough of the aneurismal sac took place." (p. 63.)

(2) The younger Cline had a case of aneurysm of the anterior tibial artery "on the upper part of the foot, and he tied the anterior tibial artery at the lower part of the leg, but the pulsation in the aneurism continued when the boy left the hospital." "It will therefore be right," says Astley Cooper, "to tie the artery by opening the sac, so as to secure it above and below the aperture, if the aneurism be seated low down in the limb, as the anastomosis with the plantar arteries is exceedingly free." (p. 63.)]

(*b*) Nouvelle Bibliothèque Médicale, 1827, Feb.

1486. In *laying bare the anterior tibial artery somewhat above the middle of the leg*, the space between the anterior tibial muscle and the long extensor of the great toe, is to be chosen and the great toe moved whilst the finger is carried outwards from the crest of the shin-bone. The skin and *aponeurosis* of the leg are to be divided for two and a half inches in the direction of this space; then with the finger, or with the handle of the knife, these muscles are separated, and at the depth of an inch the anterior tibial artery is found, with its accompanying single vein and nerve.

In the neighbourhood of the instep the artery is quite superficial, covered by the skin and *aponeurosis* of the leg, between the tendons of the *m. tibialis anticus* and *extensor pollicis longus.* If the dorsal artery of the foot is to be laid bare, a cut is made in the direction of the second toe, on the back of the foot, through the skin and *aponeurosis*, and the artery is found between the tendons of the *m. extensor pollicis* and the first tendon of the *m. extensor brevis digitorum.*

1487. The *exposure of the posterior tibial artery in the middle or in the upper third* of the leg is very difficult, on account of its depth and of the expansion of the *aponeurosis* being tightened by the contraction of the muscles of the calf. A cut is made along the inner edge of the shin-bone, for three or four inches through the skin, and the attachment of the *m. soleus* divided throughout the whole of this extent. The muscle must then be turned a little aside, and the aponeurotic expansion, separating the muscles of the calf into a superficial and deep layer, divided, under which the artery is found, between two veins, and accompanied with the tibial nerve on its fibular side (1). *At its lower part* the posterior tibial artery lies very superficial, and may easily be exposed by a cut, two inches long, between the inner ankle and the Achilles' tendon. It lies closer to the heel than the tendons of *m. tibialis posticus*, and *flexor digitorum pedis*, and is surrounded with fat and cellular tissue.

[(1) It will not be out of place here to give a caution as to the treatment of a wound of the posterior tibial artery, by any instrument or other body penetrating from the outside of the leg. I well recollect the case of a man, who whilst mowing in company with others, received the point of the scythe of the labourer next behind him, in the outside of the upper part of his leg. The scythe passed inwards, and wounded the posterior tibial artery, without piercing the skin on the inside of the leg. The wound was freely enlarged, and great pains taken to get at the vessel, but its depth was so great, that after many efforts, the attempt was given up. A cut was then made on the inside of the leg, as above directed, and the vessel reached and tied with great ease. In a similar case, the like practice should be adopted. The only difficulty in the operation consists in forgetting that the artery and deep layer of muscles are overspread with a tight *fascia*, which may possibly be mistaken for the interosseous ligament. The artery cannot be reached till this be opened very freely, as it is very unyielding.—J. F. S.]

1488. If the *peroneal artery be tied* in the middle of the leg, a cut is to be made from any one part of the outer side of the Achilles' tendon, and carried obliquely upwards and outwards to the hinder outer surface of the splint-bone. The external saphenous vein is to be avoided, the *aponeurosis* divided, and the forefinger, passed before the Achilles' tendon, is carried upon it before the muscles of the calf, so as to separate them from the deep layer. The *fascia* covering the deep muscles is to be cut through, and the inner edge of the *m. flexor pollicis* raised upwards and outwards. The artery is found sometimes between the fibres of this muscle, and sometimes between it, the splint-bone, and the interosseous membrane. If the artery be looked for deeper than the middle of the leg, as **Charles Bell** proposes, its hinder branch only is found.

1489. What has been already said about aneurysms on the front and back of the hand, applies also to those on the sole, and on the back of the foot. If here it be not permissible, on account of the position of the aneurysm, to open the sac, and tie the artery above and below, the flow of blood must be prevented by tying the affected artery still higher, and, after opening the sac, it must be completely prevented by pressure. This treatment must also be followed in wounds of arteries on the back of the foot and in the sole (*a*).

1490. When the femoral artery is obliterated at the origin of the *arteria profunda*, the blood passes from the branches of the internal iliac arteries into the circumflex arteries of the thigh, and by the descending branches of the *a. profunda* into the articular arteries, whence it passes into the trunk of the femoral. If the obliteration occur in the lower third, the circulation is kept up, not merely by the anastomosis between the *a. profunda* and the arteries of the knee, but also by many anastomotic or muscular branches. If a part of the popliteal artery, or even the origin of the upper or lower arteries of the knee be obliterated, the blood passes by the anastomosis of the *a. profunda* into the upper, thence into the lower arteries of the knee, and from them into the recurrent branches of the tibial arteries.

[The following is **Astley Cooper's** account (*b*) of the dissection of almost seven years after the femoral artery had been tied for popliteal aneurysm. "The femoral artery which is necessarily obliterated by the ligature, was here converted into a cord, from the origin of the *arteria profunda* down to the ham. The whole of the popliteal artery was also changed into a similar substance; and thus the natural channel of the blood from the groin to the lower part of the knee was entirely destroyed. The muscles therefore which usually receive blood vessels from the femoral artery, as the *sartorius*, *rectus* and *vasti*, had no branches but from the *arteria profunda* and circumflex arteries; and the articular arteries from the popliteal, although they were still capable of receiving blood, derived it, not from the popliteal artery, but from the communicating vessels of the *profunda*. The *arteria profunda* formed the new channel for the blood; considerably enlarged in its diameter, although still not equal in size to the femoral artery at the groin, it took its usual course to the back of the thigh on the inner side of the thigh bone, and sent branches of a larger size than usual to the flexor muscles of the leg, and just midway on the back of the thigh it began to send off those arteries which became the support of the new circulation. The first artery sent off passed down close to the back of the thigh-bone, and entered the two superior articular branches of the popliteal artery, which vessels supply the upper part of the knee-joint. The second new large vessel arising from the *profunda* at the same part with the former, passed down by the inner side of the *biceps* muscle, to an artery of the popliteal, which was distributed to the *gastrocnemius* muscle. Whilst a third artery dividing into several branches, passed down with the sciatic nerve behind the knee joint, and some of its branches united themselves with the inferior articular arteries of the popliteal, with some recurrent branches of those arteries, with arteries passing to the *gastrocnemii*, and lastly with the origin of the anterior and posterior tibial arteries; and these new large communicating branches were readily distinguished from others by their tortuous course. It appears then that it is those branches of the *profunda* which accompany the sciatic nerve, that are the principal supporters of the new circulation. They were five in number, besides the two deep seated arteries which do not accompany the nerve. The external circumflex was considerably larger than usual for the supply of branches to the muscles on the fore part of the thigh, but it had no branches for the new circulation. The obturator artery did not appear larger than usual, and although much pains were taken to trace any enlarged communicating branches between the ischiatic arteries and *profunda*, yet no vessels capable of receiving so large an injection could be found." (p. 254–56.)]

1491. If a vein and an artery connected with it be so injured, that by the subsequent adhesion of the edges of the wounded vessels, an immediate communication between the two vessels is produced, it is called an *Aneurysmal Varix* (*Varix aneurysmaticus*, *Aneurysma per transfusionem. A. arterioso-venosum.*) It occurs most frequently at the elbow-joint, as consequence of blood-letting; it is, however, also observed in other parts (1).

(1) On the upper arm, by **Richerand**, **Cloquet**, **Jaeger**; on the radial artery, and cephalic vein, by **Schottin**; on the subclavian, by **Larrey**; on the carotid, by **Larrey** and **Marc**; on the temporal, by **Bushe** and myself; on the femoral artery, by **Siebold**, **Barnes**, **Dupuytren**, **Breschet**; on the popliteal, by **Lassus**, **Sabatier**, **Richerand**, **Boyer**, **Larrey**, **Hodgson**; on the external iliac, by **Larrey**; and on the division of the *aorta* and *vena cava*, by **Syme**.

[My friend **Mackmurdo** has very recently had a case of aneurysmal *varix* between the internal jugular vein and carotid artery close to the skull. Its existence was not known prior to death. The man had had scrofulous enlargement of the glands of the neck near the angle of the jaw, which suppurated; a sinuous ulcer formed, from which arterial hæmorrhage occurred twice, and **Mackmurdo** thought it advisable to tie the common carotid artery which arrested the bleeding; but the patient sunk after seven days, and on *examination*, besides large destruction of the bifurcation of the carotid artery and of the internal jugular vein, the aneurysmal *varix*, already mentioned, was found.—J. F. S.]

1492. Aneurysmal *varix* is characterised by a circumscribed swelling of blue colour, and small extent, which is formed by expansion of the vein, and in which a peculiar tremulous motion, and whizzing noise are observed, produced by the overflowing of the blood from the artery into the vein. The swelling is generally, at least, at the bend of the arm, not larger than a nutmeg, (on the femoral and subclavian, it has been seen as large as an egg, and even as big as the fist,) accompanied with varicose swelling of the neighbouring veins; it subsides entirely by pressure, shows less pulsation if the part on which it is situated be raised; but is greater if the part hang down, or if pressure be made upon the vein below this swelling. If the artery be compressed above the swelling, the pulsation at once ceases, but returns directly the pressure is withdrawn. The trunk of the artery above the swelling pulsates more strongly than on the opposite side, and is much distended; below the swelling, the pulsation is weaker, but after long continuance the diameter of the artery also is increased, and the artery often becomes tortuous. The size of the swelling depends on the size of the opening of communication between the artery and vein, though the swelling usually diminishes somewhat; if the neighbouring veins be enlarged, it then increases no more, and no longer causes any particular inconvenience. In other cases, however, it is accompanied with diminution of the pulse in the lower part of the artery, with a diminution of temperature, sensation, and motion of the parts below the aneurysmal varix, which fall into a state of complete torpor.

Breschet (*a*) has proved, by careful observation and experiment, that in the *systole* the blood flows out of the artery into the vein; and in the *diastole*, out of the vein into the artery; and that, on the latter condition depend, the enlargement of the lower part of the artery, which is often tortuous, and of which, on account of its weaker pulsation, it has been falsely asserted that it is diminished in diameter, as well as the other circumstances and changes of the arterial walls, into a condition similar to that of the veins. By the passage of the arterial blood into the veins, the walls of the latter are thickened, and resemble, in a degree, those of arteries. As in the extremities, the passage of the blood from the vein into the artery takes place more readily than in aneurysmal *varix* on the neck and head; so he explains how the symptoms are milder, and why in the latter, often only during the horizontal position of the head, symptoms as fainting, and the like, occur, they being grounded on the overflow of the blood from the vein into the artery.

[**Sennertus** (*b*) is first considered to have described aneurysmal *varix*; his description, however, is only a little improvement on **Galen's** account, already mentioned. (p. 197.) He says:—"The proximate cause of aneurysm is an opening of the internal, with a dilatation of the external coat of an artery. But very commonly it is opened by a wound, when unskilful Surgeons open the artery for the vein, or the artery with the vein. Hence, the external coat being softer and more like a vein more readily unites; whilst the interior being harder, remains open, in consequence of which the blood and vital spirits endeavour to escape through the aperture, and so distending the external tunic, this kind of tumour is produced."

Dr. **William Hunter**, however, in a paper entitled "*The History of an Aneurysm of the Aorta, with some remarks on Aneurysms in general,*" published in 1757 (*c*), first drew the attention of the profession to *aneurysmal varix*. He asks:—"Does it ever happen in Surgery, when an artery is opened through a vein, that a communication of anastomosis is afterwards kept up between these two vessels. It is easy to conceive this case; and it is not long since I was consulted about one, which had all the symptoms that might be expected, supposing such a thing to have actually happened, and such symptoms as otherwise must be allowed to be very unaccountable. In his second paper (*d*) **William Hunter** says:—"We must suppose that the wound of the skin, and of the adjacent or upper side of the vein, heal up as usual; but that the wound of the artery, and of the adjacent or under side of the vein remain open, (as the wound of the artery does in a spurious aneurysm,) and by that means the blood is thrown from the trunk of the artery directly into the trunk of the vein. Extraordinary as this supposition may appear, in reality it differs from the common spurious aneurysm in one circumstance only, viz., the wound remaining open in the side of the vein, as well as in the side of the artery. But, this one circumstance will occasion a great deal of difference in the symptoms, in the tendency of the complaint, and in the proper mode of treating it: upon which account the knowledge of such a case will be of importance in Surgery.

"It will differ in its symptoms from the common spurious aneurysm principally thus. The vein will be dilated or become varicose, and will have a pulsatile jarring motion, on account of the stream from the artery (1). It will make a hissing noise, which will be found to correspond with the pulse for the same reason." (pp. 391, 392.) In the young lady's case, "there was a hissing sound, and a tremulous jarring motion in the veins, which was very remarkable at the part that had been punctured, and became insensible at some distance, both upwards and downwards." (p. 397.) In the porter, it is stated:—"There is a remarkable tremulous motion, (as well as a considerable pulsation,) both in the bag and in the dilated vein, as if the blood was squirted into it through a small hole. It is like what is produced in the mouth by continuing the sound of the letter R in a whisper. (p. 403.) This motion is not only felt, and seen distinctly, but heard, too, if the ear be held near the part; and if the ear touches the skin, the sound is much more loud and distinct. It is a hissing noise, as if there was a blast of air through a small hole, and interrupted, answering precisely and constantly to the stroke of the heart, or *diastole* of the artery. * * * The patient is so sensible of the noise, that he often finds it keeps him from falling asleep, when the arm happens to be near his head." (p. 404.)

"The blood of the tumour will be altogether or almost entirely fluid, because kept in constant motion. The artery, I apprehend, will become larger in the arm and smaller

---

(*a*) Above cited.

(*b*) Opera, vol. iii. book v. chap. xliii. p. 797. Paris, 1641, fol.

(*c*) Med. Obs. and Inquiries, vol. i.

(*d*) Ibid. vol. iv.

at the wrist than it was in the natural state, which will be found out by comparing the size and the pulse of the artery in both arms at these different places," (p. 392); the reasons for which he thus gives:—"Why is the pulse and the wrist so much weaker in the diseased arm than in the other? Surely, the reason is obvious and clear. If the blood can easily escape from the trunk of the artery directly into the trunk of the vein, it is natural to think that it will be driven along the extreme branches with less force, and in less quantity. Whence is it that the artery is enlarged all the way down the arm? I am of opinion, that it is somehow the consequence of the blood passing so readily from the artery into the vein, and that it will always so happen in such cases. That it is not owing to any particular weakness in the coats of the artery, like that in a *true* aneurysm, naturally and constantly tending to rupture, but it has rather such an extension as happens to all arteries in growing bodies, and to the arteries of particular parts, when the parts themselves increase in their bulk, and, at the same time, retain a vascular structure. * * * I presume that the derivation of blood to the arm by the wound of the artery has been the cause of the dilatation of that vessel; and that in the living body an artery will as certainly become *larger*, when the resistance to the blood is taken off, as it will become smaller when it is compressed, or, as it will shrink and become a solid cord when the blood is not allowed to pass through it at all. * * * In order to conceive how or why the trunk of the artery will become larger, in consequence of an immediate and free communication with the trunk of the vein, let us take another view of it, thus:—Suppose that instead of a simple aperture, there was a large branch added to the artery of the same diameter as the aperture, and that it ramified in the common way through some adventitious vascular part, a wen, for example, and terminated in corresponding veins, and that these ended in the common trunk of the basilic vein, every body must see, that in this case the trunk of the artery would dilate till it became proportionable in capacity to its branches; for till then the trunk would be the narrowest part of the canal,—the part where there would be the most resistance, and therefore the yielding coats of the artery would give way till the just proportion was established between the trunk and all its branches. These two cases, I apprehend, are similar as to the principal point, but differ in some particulars. In the case of an aperture, the resistance to the blood is diminished; thence it will move with more celerity; the trunk of the artery will be less enlarged, and the branches will shrink a little. But in the case of an additional branch, the resistance, I presume, would be as great as before; the celerity, therefore, would not be increased, the old branches would continue of the same dimensions, and the trunk would therefore increase still more." (p. 407–411.)

(1) LAWRENCE (*a*) observes on this point:—"The sensation is almost the same as that which is communicated to the hand by the vibration of the cord of a musical instrument, and it is particularly described by some writers, who call it a rilling noise; some call it a whizzing, and some a vibratory noise. This noise is not only heard in the swollen part of the vein, but it also extends along the course of the vessel up the arm." (p. 166) LISTON (*b*) says:—"On applying the ear close to the tumour, or listening through the stethoscope, the peculiar noise is not only felt, but heard of almost startling intensity, somewhat resembling the noise of complicated and powerful machinery softened and confused by distance." (p. 676.)

LISTON relates an excellent instance of aneurysmal *varix* in the femoral vein and artery, consequent on a deep chisel-wound in the lower part of the thigh, which at the time bled profusely, but having been stuffed and compressed, healed in course of eight days." A twelvemonth afterwards, troublesome pulsation was perceived in the part; at the same time, the veins of the leg became varicose, and a succession of ulcers formed on the lower and anterior portion of the limb. The affection attracted little attention till between twelve and thirteen years after, when he observed a considerable swelling in the site of the wound, beating strongly, and the pulsations accompanied with a peculiar thrilling sound and feel—not confined to the tumour, though strongest there, but extending to the groin along the course of the femoral vein, which was evidently much dilated throughout its whole course. Six months after, the tumour was nearly equal to the fist in size, of regular surface and globular form, pulsating very strongly, and imparting to the hams the peculiar sensation of aneurismal *varix*, remarkably distinct and powerful. The pulsation and thrilling are continued in a less degree to POUPART's ligament, and down to the calf of the leg. * * * He feels little pain, but exercise and exertion of every kind are seriously impeded." (p. 676.) Firm and constant pressure of the swelling, with uniform compression of the whole limb, were employed, and LISTON

(*a*) Lectures, above cited.

(*b*) Elements of Surgery, part ii. London, 1840.

informs me with success. There is at the present time, (April, 1846,) in St. George's Hospital, a case of varicose aneurysm in the thigh resulting from a knife-stab.—J. F. S.

WILLIAM HUNTER also points out the marked distinction between aneurysmal *varix* and false aneurysm. "The natural tendency of such a complaint," says he, "will be very different from that of the spurious aneurysm. The one is growing worse every hour, because of the resistance to the arterial blood; and if not remedied by Surgery, must at last burst. The other in a short time comes to a nearly permanent state; and if not disturbed, produces no mischief, because there is no considerable resistance to the blood that is forced out of the artery." (p. 393.) In the first case which he saw, at the end of 14 years, the swelling, nothing having been done to it, was nearly in the same state. The second case, in which the swelling had the size of a large nutmeg, so remained, when seen five years afterwards.]

1493. The *cure* of the aneurysmal *varix* may be in many cases effected by continued compression, which either effects obliteration of the artery, or brings the wall of the vein so into contact that the aperture of the artery is closed. But as this mode of treatment, if the walls of both vessels be not connected, exposes the patient to the danger of a complication with aneurysm, so may it be employed only in recent cases, and in young or thin persons, where the walls of the vessel can be sufficiently compressed, and the patient recommended abstinence from all exertion of the part, when from that evil no further symptoms are caused (*a*). But if the above-mentioned inconveniences of diminished nutrition, sensation, motion, and so on, occur, the operation is indicated, and not indeed, as by many advised, by tying the affected artery above the aneurysmal part, but according to the old method, by cutting into the sac, and applying a ligature round the artery above and below the wounded part (1).

(1) BRESCHET has, from the above-mentioned causes, proved that the tying of the artery, according to HUNTER's plan, in aneurysmal *varix*, which has existed for some time, produces only temporary improvement, but that all the symptoms soon recur, as before the operation, and render tying the artery below the wounded place necessary; as the opening of communication between the artery and vein does not close, and is kept up by the introduced collateral circulation of the previous condition. He also doubts the benefit of simply tying the artery below the wounded part, as recommended by BRASDOR.

In an aneurysmal *varix* of the temporal artery, in which, by tying the common carotid artery, I obtained only temporary improvement, STROMEYER produced a radical cure by tying the vein (*b*). He divided the *varix;* at the bottom of the sac found with trouble *a small opening,* into which he introduced a probe. He freely separated the lower part of the much-*expanded vein,* and applied two ligatures around it; a third ligature tied a vein from the *occiput,* which communicated with the sac. After the *bleeding was thus stanched,* the wound was closed with six interrupted stitches.

[The advice which Dr. HUNTER gave to the young lady was "to do nothing while there should be no considerable alteration" (p. 398) in the swelling, which she followed with advantage for fourteen years. And in the second case not a hint is given about tying the artery.

ASTLEY COOPER says :—"No operation has been required for this disease, in any case which I have seen of it, as it is not a dangerous state, either to the life, or even to the arm. It renders the arm weaker, and nothing more serious arises from it." (p. 84.)

ATKINSON, of York (*c*), however, in a large and increasing size of an aneurysmal *varix*, thought it necessary to take up the brachial artery, but the patient died of mortification.]

1494. If a vein, wounded in the way described, be not in immediate contact with the artery wounded at the same time; or if on account of the oblique position of the wound, or by the compression employed, the blood find no obstruction in flowing into the vein, the cellular tissue which connects the artery and vein expands into an aneurysmal sac by which

---

(*b*) BURCKHARDT, Archiv. der physiologischen Heilkunde von ROSER und WUNDERLICH, 1843.

(*c*) COOPER's Lectures, vol. ii. p. 84.

the two vessels communicate with each other. The vein is somewhat distant from the artery, and the blood flows from the sac into the vein and thus is formed a *Varicose Aneurysm* (*Aneurysma varicosum.*) In this case the aneurysmal sac enlarges, and, it is to be feared, will burst. Clot forms in the sac, and, together with the tremulous swelling of the vein, is felt a firm pulsating swelling, of defined extent, which, if the artery be compressed above, does not, as in *varix*, subside. The above-described symptoms are also present. Tying the artery above the sac, held by Scarpa (*a*) and Hodgson (*b*) most favourable for the cure, is for the above-mentioned reasons most uncertain on account of the speedy danger of a relapse; and tying above and below the sac is the most proper (*c*).

[William Hunter was also well aware of this form of the disease. He says:—"Another difference in such cases will arise from the different manner in which the orifice of the artery may be united or continued with the orifice of the vein. In one case, the trunk of the vein may keep close to the trunk of the artery, and the very thin *stratum* of cellular membrane between them may, by means of a little inflammation and coagulation of the blood among the filaments, as it were, solder the two orifices of these vessels together, so that there shall be nothing like a canal going from one to the other; and then the whole tumefaction will be more regular, and more evidently a dilatation of the veins only. (Such is the *aneurysmal varix*. J. F. S.) In other instances the blood that rushes from the wounded artery, meeting with some difficulty of admission and passage through the vein, may dilate the cellular membrane between the artery and vein, into a bag, as in a common spurious aneurysm, and so make a sort of canal between these two vessels. The trunk of the vein will then be removed to some distance from the trunk of the artery, and the bag will be situated chiefly upon the under side of the vein. The bag may take on an irregular form, from the cellular membrane being more loose, and yielding at one part than at another, and from being unequally bound down by the *fascia* of the *biceps* muscle. (Such is a *varicose aneurysm*. J. F. S.) And if the bag be very large, especially if it be of an irregular figure, no doubt coagulations of blood may be formed, as in the common spurious aneurysm." (pp. 394, 95.)]

In operating on such a varicose aneurysm, when, after the application of a tourniquet, the swelling is cut into throughout its whole length, and the blood absorbed with a sponge, at the bottom of the cavity is seen the aperture made by the lancet, in the hinder wall of the expanded vein. If a probe be introduced into it, it passes into a second sac, but not into the artery, which is ascertained by the ease with which the probe moves around and the difficulty with which it can be carried in the direction of the artery. After the introduction of the probe, this opening is to be enlarged, and the second sac, which is full of coagulated blood and layers of membrane, laid open throughout its whole extent. After emptying and cleaning the sac, the wound of the artery appears in the bottom, through which the sound is to be introduced, and the ligature applied above and below.

[My friend Green had some years ago a case of varicose aneurysm, as he considered it, in the frontal branch of the temporal artery and vein, about the size of a walnut, and which resulted from these vessels having been wounded in cupping. The artery entered one end of the sac, but it did not pass out at the other, so that the vein alone had two orifices in it. He removed the whole mass and the preparation is in King's College Museum.

The highly interesting case described by Perry (*d*) under the name of varicose aneurysm, does not appear to me to correspond at all with the conditions which the term varicose aneurysm generally implies, and in which it is used by both Hodgson

and **Chelius**. The former specially observes:—"If the vein be not in immediate contact with the artery, or if the blood meet with obstruction in its passage from one to the other, in consequence of the obliquity of the wound, the employment of compression, or any other cause, the cellular membrane connecting the vein and artery may be dilated into an aneurysmal sac, through which the two vessels will communicate with each other. In this case the vein will be removed to some distance from the artery, and the *aneurismal sac will be situated between the two vessels;* the blood will first pass from the artery into the aneurismal sac, and from the aneurismal sac into the *dilated vein.* This variety of disease may with propriety be denominated *varicose aneurism,* to distinguish it from *aneurismal varix.*" (p. 507.) In **Perry's** case, however, there was nothing of this kind. He says:—"At the spot in the thigh where the communication had been presumed to exist between the artery and vein there was an aneurismal sac about as large as a walnut, firmly ossified within, which, by the pressure it had exerted upon the vein, had caused absorption of its coats, so as to form a circular opening of about two lines in diameter, into which the aneurism had burst; thus inducing a free and persistent communication between the vessels. Just below the aperture, the vein was obliterated at a single point, below which it was again pervious. In all the rest of its course up the thigh it was *diminished in size* and *thickened.*" (p. 42.) From this it will be clearly seen, there was neither condition of a varicose aneurysm, neither an intermediate sac, nor a dilated vein, but exactly the contrary. Neither was it an aneurysmal *varix,* for there was no special tumour of the vein, nor was it enlarged, but just the contrary, "diminished in size and contracted." If the account of the case be carefully examined, I think it must be admitted that it is none other than a simple case of aneurysm, having the very rare termination of bursting into a vein, just as in the cases already mentioned (*par.* 1402, *note*) where aneurysms of the *aorta* have burst into the pulmonary artery, which in reality belongs to the venous system, as it conveys the spoiled blood to the lungs for purification. That so far as the femoral artery was concerned, it was subject to aneurysm by dilatation cannot be disputed, for **Perry** says "the coats of the femoral artery, throughout its whole course, were scarcely, if at all thicker than those of a vein, the attenuation having, as careful dissection afterwards proved, taken place equally in all its coats. Immediately below the origin of the *profunda* the vessel was greatly dilated, having the appearance of an aneurysmal sac. Its coats were here softened and much attenuated, large enough to admit the point of the ring-finger." (pp. 41, 42.) The ossification of the aneurysmal sac at which the artery communicated with the vein has nought to do with the question.—J. F. S.]

B.—UNNATURAL EXPANSION IN THE BRANCHES AND RAMIFICATIONS OF ARTERIES.

von **Walther**, Journal für Chirurgie und Augenheilkund, vol. v. p. 244.
Breschet, above cited.

1495. An unnatural expansion of an artery, to a greater or less extent, often throughout its whole length, and in its most principal ramifications, with simultaneous lengthening of the vessel, which becomes tortuous, and, with numerous curvings and windings, forms swellings of various size, on many parts presents knotty elevations, or little circumscribed aneurysmal swellings, which sometimes are true sac-like aneurysms, sometimes also mixed aneurysms, with torn internal coat, (**Breschet**,) produces *Branching Aneurysm* (*Aneurysma racemosum, A. cirsoideum, A. anastomoticum seu anastomosium, Varix arterialis, Tumor sanguineus arteriosus.*) It occurs most commonly in arteries of the third or fourth order; on the branches of the carotid, labial, temporal, occipital, ophthalmic, and superior thyroideal arteries; on the arteries of the fore-arm and leg; in the arterial arches on the palm and sole; and in the vessels of the *periosteum.*

1496. This aneurysm is characterized by a more or less strong pulsation of the several expanded arteries, and their various arches and branchings and by knotty, soft, livid, pulsating swellings, forming distinct tumours of various size, which lie contiguously in rows, or even upon each other.

Every increased congestion of blood by exertion, overheating, and so on, increases the pulsation, which, by compression of the principal trunk, is diminished or entirely stopped, and at the same time the swelling subsides and becomes relaxed. From the various situations of this aneurysm, to wit, on the head, peculiar symptoms may arise; the patient hears violent pulsation, has whizzing and roaring in the head, which disturb him in his sleep; often shooting pain in the course of the arteries; and if the swelling lie on a bone, it is absorbed by the pressure, or groove-like depressions are formed on it in the course of the several enlarged vessels. With the quicker or slower enlargement of the swelling, the skin thins more and more, and bleedings at last take place spontaneously, or from trifling causes, which are often difficult to stanch, are frequently repeated, and cause death.

1497. The branching aneurysm is distinguished from other swellings by the distinct pulsation and the considerable expansion of the arteries to a great extent of their course, and by the pulsation of the compressible swelling. The diseased expansion of the capillary vessels or *Teleangiectasy*, never presents any such pulsation and expansion of single vessels; but both may occur at once, the branching aneurysm may subside into a teleangiectasy, or may be developed from it. Examination of branching aneurysm shows the walls of the expanded arteries thin, soft, and falling together, when cut through, like veins, and especially resembling expanded veins. At the situation of the most knotty eminences there are either sac-like expansions of all the thinned arterial coats, or the middle coat is torn and the internal coat protruded with it through this opening under the cellular coat (*a*).

1498. The *causes* of branching aneurysm are either accidental, as wounds of the arteries, contusions, continued irritation, and thereby continued congestion, especially in suppressed ordinary discharges of blood or rheumatic affections. Most commonly there appears to be a general co-operating *diathesis;* for rarely is the affection confined to one part; mostly a more or less general affection of the arterial system shows itself, especially softening of the arterial walls, which increases in proportion to their expansion. Females of middle age and of delicate bodily frame are most frequently subject to it.

1499. The *prognosis* in branching aneurysm, when it has attained a high degree of developement, or when a general *diathesis* exists, is extremely unfavourable. The *treatment* must be directed especially to the origin and seat of the evil. With a defined extent, and when the seat of branching aneurysm is defined, a proportionate and sufficiently great compression, with rest, and the local and internal use of astringent remedies, may be sufficient (Breschet.) If the swelling be superficial, for instance, on the face, and the vessels going to it be not expanded to a great extent, they may be extirpated; this, however, is rarely the case, and the extirpation, on account of the severe bleeding, easily becomes dangerous; and in such cases, as well as in a rather large extent of swelling, its simple or manifold tying, as proposed in teleangiectasy, is proper. The simple tying of the swelling and pressure (1) is also applicable, only to a certain extent, but is always accompanied with danger of severe bleeding and irritation, which happen also from the employment of caustics and the actual cautery. Where the vessels leading to the swelling are ex-

---

(*a*) Breschet, above cited, pl. ii. fig. 3.

panded to a great extent, they, to wit, the temporal, occipital, and other arteries, have been severally tied, but their manifold anastomoses have in such cases nearly always soon produced a relapse, even when continued pressure has been kept up on the swelling. Tying the principal trunk, the branches of which are expanded, is in such cases always the most advisable, although experience also shows that even therewith a relapse frequently ensues; in which case the swelling subsides only for a short time, but soon arises again, and increases, together with the pulsation caused by the introduced collateral circulation. After tying the principal trunk it is therefore always advisable to employ a corresponding antiphlogistic treatment, cold applications and pressure (2). If the disease occur on the limbs, and in such degree that the modes of treatment recommended are inapplicable or ineffectual, amputation of the limb is the only remedy, but it rarely has a satisfactory issue.

(1) **Graefe**, in the largest pulsating swellings, made a long and deep cut, immediately pressed down firmly a large sponge, and, before the blood could escape, quickly applied a soft agaric between the edges of the wound, covered the whole with a sponge an inch thick, and confined it with strips of sticking plaster laid cross-ways and a circular bandage. The result was favourable.

(2) **Travers** (*a*), **Dalrymple** (*b*), and **Wardrop** (*c*) have, in such aneurysms in the orbit, tied the carotid artery with success, which is accounted for by the smaller and less numerous anastomoses. **Rogers** (*d*) cured an aneurysm by anastomosis of the external maxillary artery by tying the carotid. On the contrary, **Dupuytren** (*e*) tied the carotid on account of such swelling situated on the ear and region of the *occiput*, for which compression and tying of the temporal, auricular, and occipital arteries had been performed without success; the swelling diminished, the pulsation ceased, but it returned about the seventeenth day, and continued, only less strong than before, in spite of a compressing apparatus. **Mussey** (*f*) tied both carotids, on account of such swelling upon the crown of the head, with little benefit, as the pulsation recurred four weeks after the second tying; and in the extirpation which was performed two quarts of blood were lost, and forty vessels tied. With equally various result was the carotid tied. (**Dupuytren.**) I have seen one case, where the femoral artery was tied without benefit, and amputation of the thigh became necessary.

1500. With branching aneurysm in the soft parts, those swellings which depend on similar diseased changes of the arteries in bones, actually agree, and are therefore distinguished by **Breschet** as *Aneurysm of the arteries of bones*, and by **Scarpa** as *Aneurysms by anastomosis of bones.*

Pearson (*g*) communicated the first observations on such swellings, and after him **Scarpa** (*h*). More recently **Lallemand** has made known a similar observation; and **Breschet** (*i*) has added remarks, as well as historical inquiries upon the existence of similar cases in the earlier writers, with several observations by **Dupuytren.** **Scarpa** (*j*) also has subjected this disease to a special inquiry.

1501. Frequently, from sudden and undiscernible causes, often a shorter or longer time after the operation of any external violence, more or less severe pain occurs upon some one spot of a bone, most frequently in the neighbourhood of the joint-ends of tubular bones, which, when the patient is quiet, diminishes, or even for a time subsides; but then returns more severely. A swelling appears, the veins of the whole limb swell; the pain spreads over the entire limb, which has a bluish-red colour.

(*j*) Annali Universali di Medicina. May, June, 1830.

Pulsation is soon felt in the swelling, which is at first indistinct, but subsequently becomes stronger, and as strong as in aneurysm. This pulsation is synchronous with that of the artery, without a rush, and, if the disease have previously made much progress, with extension of the swelling in every direction. Pressure on the principal artery of the limb, between the swelling and the heart, completely stops the pulsation, by which the swelling loses its tension and subsides, but returns immediately the compression of the artery is removed. The patient has often continued pain in the affected part, which is swollen or wasted, and the motions of which are entirely, or only at the joint, in the neighbourhood of which is the swelling, prevented. If the swelling be pressed with the fingers, there is often observed at some parts a crackling, as in squeezing parchment together, or in breaking an egg-shell. If the bone be completely destroyed, the part may be moved in every direction (*a*). If the swelling be developed in the neighbourhood of a large artery, it may most commonly be followed over the swelling.

Nicol (*b*) has communicated a case precisely like mine.

1502. On examining these swellings after death or amputation of the affected part, the principal vessels have been found throughout their whole course unhurt, and neither by injection nor by the closest examination could any trace of disturbance of their continuity be observed. On opening the swelling, the condition of the parts varied according to the different degree of development of the disease. When the bone was entirely destroyed, the aneurysmal sac, of which the walls were very thick, often cartilaginous, and formed of *periosteum*, contained a quantity of fibrous layers, like those commonly found in aneurysmal sacs, and in it the remains of the destroyed bone. The internal surface of this sac was flocky, irregular, very much like that part of the *placenta* connected with the womb, and presents numerous openings of freely branching vessels, from which, if the part be injected, a portion of the injection flows into the sac. In a slighter degree of the disease the external table of the bone was still found, but very thin, destroyed in some places, in others but slightly resisting the pressure of the finger, resembling a cartilaginous plate, which yields to pressure and again rises, or breaks like an egg-shell. The neighbouring joint was always healthy, even when separated from the aneurysmal sac only by the layers of the loosened joint cartilages. The fibrous clot was collected in the cavity of the bone, or the sac presented several cavities filled with it, wherewith every single artery of the sac corresponds. Upon the external surface of the sac the arteries were very numerously expanded and enlarged, and often were so to a tolerable distance around the sac.

1503. These swellings are developed on the various bones of the body, not unfrequently on several bones of one and the same person; on the skull, trunk, and limbs, most frequently on the upper part of the leg, below the knee, on the shin, or splint bone alone, or on both bones at once (Pearson, Lallemand, Dupuytren); but hardly ever in the middle of the long tubular bones.

The *occasional causes* of these swellings are commonly external violence, a kick, blow, fall, or any violent exertion in lifting a heavy weight,

---

(*a*) Chelius, Zur Lehre von den schwammigen Auswüchsen der harten Hirnhaut und des Schadels. Heidelberg, 1831. fol. Erste Beobachtung, p. 43.

(*b*) Edinburgh Medical and Surgical Journal, 1834. July.

and so on, in which the patient feels a crack at the spot where subsequently the disease is developed; the interval, however, between the operation of such cause and the origin of the disease is very great, and during this time the patient often feels no pain, or only indistinct and transient pain. **Lallemand** observed this disease occur after acute rheumatic swelling of the knees. Ordinarily the swelling has a general internal cause, manifestly corresponding with which is its not unfrequent origin without any distinguishable cause, the simultaneous or subsequent origin of several happening in one and the same subject, and especially the circumstance that the disease even reappears in some parts after amputation of the affected limb. On these grounds such swellings cannot be placed, as they have been by **Breschet** and others, in the same rank with teleangiectasy of the soft parts, which is always a local disease, and so remains, even when of considerable extent, whilst this, on the contrary, is usually connected with a constitutional disease.

1504. These diseased changes in the bones appear always to be preceded by an inflammatory condition, in consequence of which the nourishment of the bone is altered; loosening, softening, and absorption of the hard bony mass, a more rich development and enlargement of the vessels, congestion of blood, and complete destruction of the bone are produced. That these diseased changes proceed from the interior to the exterior of the bone, is admitted by all observers, and the cases in which the external plate of bone has been found similar to a thin fragile shell, prove it. But whether this disease be not also developed from the external surface of the bone and from the *periosteum*, and whether the condition of other organic diseases of bone be not changed by an angiectasic complication, as in these swellings, must be decided by further examination and observation.

[It must not be supposed that all pulsating tumours in bone are to be referred to the peculiar form of disease now under consideration, for **Stanley** (*a*) has shown that "three distinct sources of pulsation in such tumours can be recognised. *First.* The proximity of a large arterial trunk. *Second.* The development of blood vessels and blood cells, constituting a sort of erectile tissue within the tumour. *Third.* Enlargement of the arteries of the bone in which the tumour has originated." (p. 303.) Of the first kind he mentions several examples, in two of which "the tumour occupied the whole circumference of the upper arm in its upper third, and possessed throughout an equal and strong pulsation, which ceased on compressing the subclavian artery above the clavicle. In each case the disease was considered to be an aneurism of the axillary artery." One of these cases was, on *examination,* found to be "an encephaloid tumour originating in the *humerus,* and covered by the articular cartilage of the head of the bone. * * * There were no large vessels distributed through it. In the other case, the tumour originated in the *humerus,* and was composed of a firm gelatinous substance, about half an inch thick, and forming the walls of a large cavity, filled by a serous fluid. * * * In this instance no remarkable disposition of vessels through the tumour was observed. * * * In both these cases the brachial artery was perfectly healthy and with its accompanying veins and nerves was found closely united by cellular tissue to the tumour through its whole extent." In a third case, which was under **Lawrence**'s care, and following a fall, "shortly afterwards a painful swelling arose immediately above the knee, and gradually extended around the back part and sides of the lower third of the thigh. Near the tendon of the *biceps,* a softening of the swelling indicated the probability of its containing matter, and accordingly a small puncture was here made into it from which about four ounces of arterial blood freely flowed. On examining the swelling more closely, pulsation in it was now discovered." On consultation it was presumed to be an aneurysm, the femoral artery was therefore tied, the pulsation ceased, and the size of the swelling at first diminished but afterwards it again "enlarged, became painful, and the skin covering it sloughed, the sloughing extended deeply into the tumour, but was

---

(*a*) On the Pulsating Tumours of Bone, with the account of a case, &c; in Med.-Chir. Trans., vol. xxviii. 1845.

unaccompanied by hæmorrhage. * * * He shortly afterwards sunk from exhaustion." On *examination*, "the tumour was found to consist of a compound of soft fibrous and dense osseous tissue, the latter situated deeply, and extending around the *femur*, in which it appeared to have originated. The whole series of femoral, inguinal, and lumbar absorbent glands were converted into osseous tumours. The femoral and popliteal arteries were sound. In the lower part of the thigh, the femoral artery was a little compressed and displaced by the ossified absorbing glands which were closely united to it." (p. 304–306.) Under this head STANLEY mentions two cases of HODGSON'S, of encephaloid tumours in the *tibia* just above the inner ankle, of which HODGSON observes:—"To what these tumours owed their pulsation I know not, but I thought it was derived from contiguous arteries." Also a case of LAWRENCE'S (*a*) of "medullary tumour developed in the head of the *tibia*, attended at one period with pulsation and suppression of the pulse in the anterior and posterior tibial arteries at the ankle. In the account of the examination of the limb, Mr. LAWRENCE states that the medullary tumour had protruded from the bone just at the division of the popliteal artery, and the passage of the anterior tibial through the interosseous ligament," which "circumstance accounts for the pulsation felt in the tumour at an early period; for the suppression of the pulse in the tibial arteries when the morbid growth was confined by the *fascia* of the leg, and its subsequent return when the progress of the swelling through the *fascia* had liberated the arteries from pressure." STANLEY also refers to a case of GUTHRIE'S (*b*), in which there was a tumour on the *nates* as large as an adult's head, which was considered to be an aneurysm; "the pulsation was decidedly manifest in every part; and, on putting the ear to it, the whizzing sound attendant on the flowing of blood into an aneurism could be very distinctly heard. * * * The ligature of the common iliac was followed by a diminution of the tumour to the extent of one half, and the recovery from the operation was complete. Five months afterwards the tumour again enlarged, and she gradually sunk. On *examination* the tumour was found to be composed of cerebriform substance. The arteries were healthy." Of the *second* kind, was STANLEY'S own case:—"The pulsating tumour originated in the *ilium*, it was soft, spongy, and dark-coloured, with cells dispersed through it, each about the size of a pea, and filled with blood. Bunches of convoluted vessels were drawn out of this spongy substance, and, when macerated, this substance was reduced to a tissue closely resembling that of a swelled spleen or *placenta*. Here was a structure capable of enlargement by the distension of its vessels and cells; and, assuming these to have been directly continuous with the arterial system, it may be added, that the rush of blood into such a structure would give to the whole mass a pulsation resembling that of aneurism; at all events, it is certain that this tumour did possess such pulsation, which ceased directly the *aorta* was compressed through the abdominal parietes; moreover, that the tumour enlarged and became tense when the femoral artery below it was compressed, as an aneurism, under similar circumstances, would have done." Similar to this, is the case given to STANLEY by the younger LAWRENCE, of Brighton, in which the tumour in the right groin having "gradually increased to the size of an egg, was then observed to pulsate, after which it rapidly increased. The pulsation continued, was uniform over the whole tumour, and accompanied by a distinct bruit." The man died, and, on *examination*, the tumour was found to consist "of vessels intermixed with soft gelatinous substance. The vessels formed more than half the tumour, were about the size of sewing thread, and very convoluted; and were directly continuous with the arterial system." (pp. 309, 310.) The *third* form is the disease which BRESCHET and SCARPA here refer to, and with the cases which they have given must be included LUKE'S case, which STANLEY relates, in which a man of 20 years broke his thigh; "at the end of seven weeks it was firmly united. A month afterwards, by a second accident, the bone was again broken at the same place. Reunion of the fracture ensued, but very slowly and unevenly. A tumour now formed in the situation of the injury; it was hard in some parts, soft and elastic in others. A grooved needle was introduced into it, and a jet of blood followed. The tumour increased to the size of a large melon, became very painful, and pulsation in it was now discovered. Suspicion of its being an aneurism in consequence arose, and in consultation it was determined to tie the femoral artery; this was done with the effect of stopping the pulsation of the tumour, and producing a diminution in it to the extent of an inch in its circumference. About a month afterwards the tumour again enlarged, but without the return of pulsation, and it was now deemed right to amputate the limb. The surface of the stump bled so profusely, that more than 40 ligatures were required.

(*a*) Observations on Tumours; in Med.-Chir. Trans., vol. xvii. p. 39. 1832.

(*b*) London Medical and Surgical Journal, vol. v. p. 831, 1834; and vol. vi. p. 101, 1835.

The medullary artery was greatly enlarged, and threw out a forcible jet of blood. The man left the hospital with the stump healed, and in every respect well. On *examining* the limb, the lower third of the *femur* was found expanded into a spherical tumour, in the interior of which were cells of varying size, some of the largest about an inch in diameter, and filled with blood. The femoral and popliteal artery were entire and healthy." (pp. 311, 12.) Although STANLEY places this case among the third kind of pulsating tumours, yet it seems, from the history, that it has greater resemblance to the second.

From the recital of these cases, one important point immediately attracts attention, which is, the absence of any peculiar character by which either form of swelling could be distinguished from aneurysm, for which they seem to have been almost universally mistaken.—J. F. S.]

1505. In *treating* this disease, in some cases applications of various kinds, leeches, rubbing in, mercurial treatment in presumed syphilitic diseases, and so on, have been employed, but without any result. Only can a strict and sufficiently long continued antiphlogistic treatment, with attention to the general causes standing in somewhat causal relation, perhaps prevent the development of this disease. If the swelling have already acquired a certain stage, according to our present experience, *tying* the principal arterial trunk, or *amputation* (if the situation of the disease permit) can alone effect a cure.

1506. Tying the principal trunk of the artery gives the more hope, according as it is undertaken early, even before considerable destruction of the bone has taken place. LALLEMAND'S case proves that a permanent cure may be effected ; but when the diseased change in the bone has so far advanced, only temporary diminution of the swelling and removal of the aneurysmal symptoms are effected, whilst the *disease* of the bone continues spreading, as shown by DUPUYTREN'S (*a*) case, in which, seven years after the femoral artery had been tied for such swelling at the upper part of the shin-bone, amputation was required, as, without the reappearance of any aneurysmal symptoms, it had attained an enormous size. In all cases where the destruction of the bone has already far advanced, amputation can only be considered as a means of deliverance ; it must not, however, be herein overlooked that with existing constitutional disease, even after the operation, without any cause, the disease may be set up again, as shown in SCARPA'S (*b*) first case, in which, five years after amputation, during which time the patient's health was good, the disease, without any cause, again showed itself on the stump of the thigh-bone.

von **Walther**, Ueber Verhärtung, Scirrhus, harten und weichen Krebs, Medullarsarcom, Blutschwamm, Teleangiektasie, und Aneurysma per Anastomosin; in Journal für Chirurgie und Augenheilkunde, vol. v. p. 189.

1507. By the unnatural expansion of the capillary vessels are produced soft elastic swellings, which, consisting merely of numerous vessels tortuous and connected together with loose cellular tissue, can in respect to their internal structure, be compared with nothing better than the *placenta.* The different designations, *Fungus hæmatodes, Tumor fungosus sanguineus, Aneurysma per anastomosin, Aneurysma spongiosum, Blutschwamm, Teleangiektasie, Tumeur érectile, Splenoide* have been applied to them.

I consider *teleangiectasy* the best of all these designations. The term *bloody fungus (Fungus hæmatodes)* I employ here, *but not in the sense of* Hey *and others, who thereby designate another degeneration,* for which I consider the term *Fungus medullaris* more appropriate; at least, I cannot, after numerous examinations, admit (as Walther does) any other *Fungus hæmatodes* besides teleangiectasy and medullary fungus.

1508. These swellings, which originally have their seat in the skin and underlying cellular tissue, occur either in children or adults, or are congenital. It generally begins with a red or bluish spot, which at first is little or not at all elevated above the skin, and increases in a shorter or longer time to a variously shaped swelling, in which the patient feels a peculiar crawling and beating, which on closer examination may be more or less distinctly perceived. The colour of the swelling is sometimes more red, sometimes more bluish; it enlarges and pulsates more distinctly at every exertion, by which the circulation of the blood is quickened. When it has attained a great extent, single fluctuating spots arise, the skin thins, bursts, and considerable bleeding ensues, which frequently recurs. The apertures often close with a seemingly firm scar; and often red, fungous granulations spring up from them, which consist merely of clotted blood. The interior of such swelling exhibits a convolution of innumerable vessels enveloped in loose cellular tissue, many cavities filled with blood, and frequently single vessels full of holes, out of which the blood trickles. If these swellings exist in the cellular tissue beneath the skin, the latter retains its natural condition for a longer time; a deceptive sensation of fluctuation is felt; the skin is gradually altered in the way mentioned; the disease rarely extends between the deep-lying organs Swellings of this kind may be very easily mistaken for *fungus medullaris.*

The fungous growths, after the bursting of teleangiectasy, result from clotted blood and considerable development of the *parenchyma* of the swelling; but there never exists in them any specific degeneration (a transition into *fungus hæmatodes,* according to Walther's opinion) if no definite general dyscrasy be present. I have seen many bursten and fungous teleangiectasies, but never any extension to a distant organ, as in medullary *fungus.* Also in this degree, if teleangiectases arise after local diseases, they especially affect the constitution by repeated loss of blood. Upon this, also, depend the favourable results produced by suppuration and scarring, as also the circumstance that bursten teleangiectasies are often closed by a tough scar.

1509. These swellings originate in an unnatural extension, and certainly also in a large development of the capillary vessels; but since these must be considered as the terminations of the arterial, and the commencement of the venous system, we find in such swellings both, but sometimes the arterial, sometimes rather the venous side of the capillary-vascular system affected. This difference manifests itself by the appearance of the swelling, and the circumstances accompanying its development. In teleangiectasy, which affects rather the arterial side of the capillary system, the redness is brighter, the pulsation more distinct, and the enlargement more rapid; but in the venous blood-*fungus* the redness is more dull, bluish, the pulsation less, frequently not at all perceptible, and the growth slower.

Jaeger's assertion, that teleangiectasy never exhibits pulsation, and that this is only the case when it is accompanied with *Aneurysma anastomosium,* is incorrect. Certainly, it never is perceived in flat though extensive teleangiectasy, but it certainly is, when it has risen up to actual *swelling,* and especially in great agitation of the vascular system, when the crawling pulsation is perceptible even to the patient himself.

1510. Besides the considerable ramification and development of the vessels, various changes may also arise in such swellings from thickening and degeneration of the uninjectable part of their cellular tissue, whereby the swelling varies more or less (1) from that above described. Teleangiectasy may also, especially by continued irritation, be accompanied with *aneurysma anastomosium,* if situated where there are numerous arterial ramifications and anastomoses. Teleangiectasy then increases more rapidly stronger pulsation is felt in the neighbouring branching arteries, and the pulsation in the swelling itself even, is greater (*par.* 1496.)

(1) I have seen one such teleangiectasy between the thumb and metacarpal bone of the forefinger, as a dusky red swelling, expanding at certain parts into thin blood sacs, with crawling pulsation, additional swelling, and redness in hanging down of the hand, and diminution of these appearances on raising the fore-arm, or compressing its vessels or the swelling itself with the fingers, in which the sac felt as if full of wool. I applied to it the name of *Teleangiectasis lipomatodes.* Tying the radial artery diminished the extent, and all the other appearances of the swelling (*a*).

1511. The causes of this disease are obscure. It occurs at all ages, and in all constitutions, though most commonly in young subjects of flabby habit, in children, and women. It is developed in all organs, but especially on the upper part of the body, in the skin of the skull, of the cheeks, of the eyelids, and on the lips. A contusion frequently gives rise to it.

I must deny von Walther's assertion that teleangiectasy must be always congenital, because that peculiar vascular development, and alteration of the injectable part of the substance of the organ, which happens in teleangiectasy, cannot arise at a later period of life, if it be not a vice of the first formation during the embryonic state, although unapparent; for I have often seen teleangiectasy commence and be developed in the skin of adults, without any preceding trace; but in such instances the progress will be, for manifest reasons, always exceedingly slow.

1512. Teleangiectasy is throughout a local disease, and the *prognosis* is guided by the nature and condition of the swelling, by its seat, and origin, by the age and constitution of the person affected with it. The congenital red spot often enlarges very quickly after birth, often later; but its enlargement is always to be dreaded at the period of puberty, when even the swelling, whose growth is already determined, at that time acquires increased extent. Bleeding has also been observed from such swellings at the time of menstruation. These teleangiectases have, however, a spontaneous retrocession, and are capable of cure, as I have observed, at different periods of time, in congenital teleangiectasy; and even frequently in those cases in which, from the pale red colour, a quicker enlargement is to be feared. When this occurs, the colour becomes paler; instead of the uniform redness, single vessels appear, between which the skin gradually acquires its natural condition, and the single vessels shrink, so that no trace of the disease remains.

1513. The *cure* of teleangiectasy may be effected by *compression,* by

---

(*a*) Heidelberg Med. Annalen, vol. i. p. 101. pl. iv.

removal either by *extirpation* or *tying*, by *destruction* with *caustic* or with the *actual cautery*, by exciting a *pretty violent inflammation and suppuration*, and by *tying the principal trunk of the artery*, with the branches of which the swelling is connected. The choice and preference of the several modes of treatment depend on the condition and seat of the disease, and we must be especially careful in the selection of these, that the teleangiectasic tissue be capable of sufficient inflammation and suppuration, and that the scar thereby produced can be converted into a tough tissue, with obliteration of the vessels, without it being necessary to destroy or remove it entirely.

1514. *Compression of* teleangiectasy, either alone or in connexion, at the same time with astringent remedies or cold, can only be employed in a slight degree of the complaint, in congenital red spots, if their seat permit it, with some degree of success (*a*). I have, however, from this mode of treatment, frequently as I have tried it, never obtained any satisfactory result.

Abernethy (*b*) recommends pressure, and if this be inapplicable, the application of cold rose water and alum. I have instituted several experiments with kreosote, but have never observed the slightest result (*c*). Compression has been used, according to the different seat of the disease, with flat plates and stirrup-shaped compressors, and even with plaster of Paris.

1515. *Extirpation of teleangiectasy* with the knife, is always accompanied with more or less considerable bleeding; as, if the patient be young, and the seat of the disease such that it is not possible to complete the operation quickly, the danger may be imminent and even fatal. Every thing depends on the cut which is carried round the swelling being made at sufficient distance from it in the healthy parts, as otherwise, on account of the very numerous and largely-distended vessels, severe bleeding ensues; and if a part of the swelling be left, its recurrence is to be feared. If it be requisite to leave part of the swelling, the actual cautery must be applied, or caustics with subsequent pressure, in order to cause destruction, and at the same time to stanch the bleeding. After extirpation, the wound is to be treated according to the general rules. This treatment is often tedious, because frequently no satisfactory suppuration ensues, and the edges of the wound long continue loose. In large and flat teleangiectasies, therefore, extirpation can never be employed, but especially only in those which are elevated and have a narrow base.

I have known two instances in which children died upon the operating table in extirpating a teleangiectasy from the face; and, at least in one of the cases, no one could doubt the capability of the highly-distinguished operator.

1516. *Tying a teleangiectasy* has always this great advantage over extirpation, that nothing is to be feared from bleeding. Its employment is specially applicable to projecting swellings with narrow base; but even in the large and out-spreading teleangiactasies, which are prominent, this mode may, according to White (*d*), Lawrence (*e*), and Brodie (*f*), be employed with the best result, as has also happened to me in several cases. Lawrence penetrates the base of the swelling with a strong, slightly-curved needle, carrying a double thread, which is firmly tied on both sides. As soon as the mass of the swelling blackens, it may be cut off with the knife, and the ligature removed. Brodie thrusts a hare-lip

(*a*) Roux, above cited, p. 248.

(*e*) Ibid., p. 420.
(*f*) Ibid., vol. xv. pt. i.

needle through the swelling a quarter of an inch from its edge, and a straight needle with a double thread at a right angle with this needle and beneath it; the double ligature is then separated, and each tied under the first needle.

[I prefer **Brodie**'s method with the two needles, as thereby the whole base of the swelling is more completely included within the thread. If the swelling be large, it will not be possible, at once, to compress it with the ligature, so as to stop the circulation and cause sloughing. In such case it is better to take hold of the middle of the tumour, and having lifted up and squeezed it, so as to empty out the blood, to pass a needle, armed with double thread, through its base. The threads are then to be carefully separated, and each pair of ends being carried round the half bases of the tumour, are tied firmly on opposite sides, and then attached to **Graefe**'s little screw tourniquet, a most excellent instrument for the purpose, with which, as the threads, ulcerating the skin, become loose, they are to be every day or two tightened, till the strangulation and mortification of the swelling is effected. In this way I operated, six years ago, on a child, twelve months old, who had teleangiectasies on the temple and ear. She was born with one, about the size of a sixpence, and bright-coloured, on the temple, just above the auricle, which soon became sore, and occasionally exuding a few drops of blood. In the course of nine months, it acquired the size of half-a-crown. When the child was about six months old, two other little ones, about as large as a pin's head, were noticed on the ear, one on the back of the *helix*, and the other on that of the *concha*. All continued growing, but were flat and distinct from each other for the next three months, when they began to rise above the skin, having previously been flat, and soon ran into one another, forming one mass. The principal and most elevated portion was on the head, immediately above the auricle, extending back on the occipital bone, as large as a crown piece, and gradually rising towards the centre, which was half an inch above the surface of the skin. From the lower part it continued on the auricle, covering the top of the *concha*, spreading over the upper part of the *helix*, and turning round upon the front of the ear, as low as the *tragus*. The pulsation in the temporal portion was very distinct; the vessels could be easily emptied by pressure, but immediatly on its removal the tumour resumed its usual size, and swelled out when the child cried. Its colour was bright scarlet, and it had the feel of a mass of small vessels, or rather that of a sponge. The temporal portion was operated on, as I have advised; but although the ligatures were tightly drawn, strangulation could not be effected; the bright colour remained, and the tumour swelled when the child cried; **Graefe**'s screw was attached, and the threads drawn as tight as possible, but without change. On the *third* day, serum freely oozed from the surface; and on the day following the ligatures were hidden, but with scarcely any appearance of having cut into the base, and the bright colour remained. The screws were tightened, but no change followed. On the *seventh* day, the ligatures had begun to cut through, and there was a free discharge from the track, but the granulations of the skin were inosculating with the under surface of the tumour, which seemed hardly at all separated. On the *eleventh* day, the screws were again tightened, but without producing any change in the appearance of the swelling. On the following day the hinder ligature came away, but no part of the tumour separated with it; a piece of lint was gently insinuated beneath it. On the *thirteenth* day, the whole swelling appeared about to fall off; it was a little shrunk, but the bright-red colour still remained. On the *sixteenth* day, it came off, leaving a granulating surface which slowly healed and contracted. The child was at this time taken into the country, with the promise of bringing her back again, to have the remaining part on the auricle, which thrust it away from the head, and turned it down at right angle, operated on; but I regret that she never returned. So far, however, as it went, the operation was completely successful.—J. F. S.]

1517. The *destruction of teleangiectasy by caustic* is, in all cases, to be considered as the most proper, where the swelling is broad and superficial, especially in children, as here extirpation with the knife is accompanied with difficulty, and speedy danger of imminent bleeding; and often, on account of the seat of the disease and the delicacy of the child, can be as little relied on as the ligature. The most proper caustic is caustic potash, applied as a paste in an aperture of sticking plaster, put on around the teleangiectasy, or smeared over the part to be destroyed, for the purpose of making a slough of sufficient thickness and size, and then covered with sticking plaster. When the slough is thrown off by suppuration, it is to be treated simply as a suppurating part; healing follows with a corresponding scarcely perceptible scar. In very much spreading teleangiectasy, if on the first cauterization, the disease be not entirely destroyed, and show itself afresh, I have never noticed its quicker spreading, and it is always cured by repeated cauterization. In adults, I have also employed HELLMUND's remedies for destroying teleangiectasy with the best result; it must, however, be recommended for children always with great caution, as, in its extensive application, the possibility of absorption of the arsenic is not to be denied (*a*). The application of caustic potash is especially efficient in congenital teleangiectasy, which appears as little superficial red spots in the skin, by which they may be certainly removed, as every other treatment is declined by the parents on account of the inconsiderable appearance of the disease. The application of caustic potash is, on every account, to be preferred to the actual cautery.

[I have not had much opportunity of watching the result of this practice, as I always either remove a teleangiectasy with a ligature or the knife; but from the few instances I witnessed, I am not inclined to hold so high an opinion of it as does CHELIUS. In one case, especially, in which a great part of the *scrotum* of a child was affected with this disease, the application of muriatic acid, to produce constriction of the vascular mass, had only the effect of exciting irritation and hastening the growth, so that it soon acquired the bulk of an orange. It was then removed by a double ligature, excepting a very small portion, which occupied six weeks, as the ligature was not kept tight. Caustic potash was then applied over the whole granulating surface, after which the sore was allowed to heal; but the vessels were soon again found to enlarge, as well as the little portion of the swelling which had been left. The muriatic acid was again applied, but as unsuccessfully as before, and was followed by abscess, on the healing of which the swelling soon re-acquired the size of an orange, and occasionally bled. I unfortunately lost sight of the case, so that I know not how it terminated, but it was quite evident the use of acid in this way was fruitless.

I certainly would not on any account apply caustic to produce an eschar in cases of this kind, and of large size; as sloughing in children, when once set up, is not always controlable and often dangerous; and a small tumour can be removed with greater readiness, and with less pain, by ligature or the knife, than by caustic.—J. F. S.]

1518. *For the production of a sufficiently violent inflammation and suppuration, to consolidate the tissue of the teleangiectasy and convert it into a mass of scar*, various remedies have been employed. *First*, the frequently repeated and slight touching the teleangiectasy from its circumference towards its centre with caustic potash; by which, after every falling off of the thin slough, suppuration is kept up for a longer time. *Second*, in children who have not been yet vaccinated, the introduction of the cow-pock into the teleangiectasy; several slight punctures are to be made into it and its neighbourhood with a lancet moistened with lymph, and at regular distances apart. If there be bleeding, some lymph is to be at once introduced into the wound with a lancet, and even some folds of linen, steeped in the lymph, applied to the teleangiectasy. Vesicles form in the ordinary manner, and after the slough falls off, the teleangiectasy has ceased (*b*). Similar to this treatment is the application of the *ung. seu emplastr. tartari stibiati* (HICKMANN); after the production of pustules, poultices are to be applied, and after separation of the slough, the parts are to be touched with lunar caustic, and bound up with sticking

---

(*a*) Heidelberg. klinische Annalen, vol. iv. p. 499, vol. iii. p. 331.

(*b*) HODGSON; in Med.-Chir. Review, vol. vii. p. 280.—Lancet, vol. xii. p. 760.—YOUNG; in Glasgow Med. Journal, vol. i. p. 93.—DOWNING; in Lancet, vol. ii. p. 237.

plaster. *Third*, the practice recommended by Marshal Hall (*a*), of piercing with a fine needle through the whole mass of the teleangiectasy, close to the sound part, and its repetition in from eight to ten different directions. The punctured canals heal and the tissue is thereby changed. Where possible, pressure may still be employed, but it has no particular effect. *Fourth*, according to Lallemand (*b*), cutting into or cutting out a piece of the teleangiectasy, and uniting the edges of the wound with the twisted suture, or the introduction of long and thick needles through the swelling, which are not however used for twisting round the thread, but their points only bent up, and the part defended with a proper covering. When the needles have suppurated out, if the swelling still continue, they must be introduced again. We need not be uneasy at the bluish, almost blackish, appearance of the swelling immediately after the introduction of the needles; it is a good sign that the inflammation will attain sufficient height. A frequent repetition of the lunar caustic is necessary; perhaps the application of nitrate of silver is better. *Fifth*, the introduction of a seton by means of a needle, through the teleangiectasy, by which the bleeding from the needle-stab is stanched, and by it remaining in a proper degree of inflammation and suppuration is produced (*c*). If the latter do not occur, some irritating injection should be thrown into the puncture, as Lloyd (*d*) has recommended, without the previous introduction of a seton. The advantage of this, as well also as of Hall's practice is that the skin upon the swelling is preserved and a smaller scar made. Of these different modes of treatment, which are especially employed in flat and spreading teleangiectasy, I must, after considerable experience, give the preference to the cauterization which I have proposed (1).

(1) In a case of teleangiectasy spreading over the whole right side of the face, and nearly over the entire upper lip, and which at several parts, especially on the upper lip, was very puffy and prominent, after all other means had been quite useless, I entirely removed it, and converted it into a smooth mass of scar by very frequently repeated cauterization with nitrate of silver, by which the upper lip was at the same time brought back to its natural thickness.

[Pattison (*e*), of New York, in a case of teleangiectasy as big as a pigeon's egg, on the shoulder of an infant eleven months old, varied Hall's operation, by passing "needles made red hot with a spirit-lamp, in rapid succession, about twenty times, into the tumour in all directions. There was no hæmorrhage, and the child apparently suffered little pain. The operation was repeated twice afterwards, after intervals of a week, and in the course of a month the tumour had entirely sloughed away, and the part healed without a vestige of the diseased structure being left."

Smith (*f*), of Baltimore, recommends the introduction of threads soaked in a solution of lunar caustic, and dried at the fire, by a needle passed through the base of the tumour at different parts.

Tyrrell was in the habit of injecting these teleangiectasies with strong solution of alum, first making a puncture with a lancet, and then inserting an Anel's syringe. The operation generally required repetition two or three times; after each of which the swelling became more and more solid, and subsequently shrunk away. No inflammation of consequence ensued.—J. F. S.]

1519. If the seat and extent of the teleangiectasy admit neither of the prescribed treatments, or if they be employed without benefit, or if ex-

pansion of the anastomosing branches of the arteries exist at the same time with the teleangiectasy, the final remedy is tying the principal trunk of the arteries with which the swelling is connected, and if this be insufficient in teleangiectasy of the extremities, amputation of the affected part must be performed. It is always advisable to apply a ligature before proceeding to amputation, as the latter can always be done if the former fail and the swelling increase, after the vessel has been tied, by the collateral circulation; it is therefore of the utmost importance to apply the ligature as near as possible to the swelling. In extensive teleangiectasy on the head, experience shows that tying the common trunk of the carotid artery even on both sides, has rarely permanent result.

Besides the early-mentioned cases of tying the carotid artery on one and both sides, (*par.* 1436,) and in branching aneurysm, (*par.* 1200,) compare also the case of a very large teleangiectasy on the ear, in which tying the carotid artery produced only momentary benefit (*a*). MOTT in a child of three years old obtained only imperfect result from tying the carotid artery, and subsequently tied the carotid on the other side. MÖLLER, in a child of four years old, tied both carotids with success (*b*). I knew a case, where in very extensive teleangiectasy of the ear and its neighbourhood, tying both carotids, continued pressure and deep cuts which were successively made in the sound skin in the neighbourhood of the swelling, to produce a satisfactory scar, had no permanent result.

When JAEGER (*c*) asserts that amputation in simple teleangiectasy is never necessary, and that where undertaken it would not succeed on account of *fungus*, I must deny this assertion. Teleangiectasy is of itself able, without branching aneurysm or other degeneration, to attain so frightful an extent, that no other means than amputation remains. I have seen one case in which a teleangiectasy showed itself after birth, as a small red spot in the middle of the upper arm, and in six months the frightful spreading had reached over the whole arm, from the elbow up to the shoulder and shoulder-blade; but the parents of the child would not decide on permitting anything to be done for it. In the case of an extensive teleangiectasy on the knee, which I formerly mentioned, where tying the femoral artery was unsuccessful, amputation was the only means of restoring the patient.

The *Tattooing* of moles on the skin, proposed by PAULI, has yet to be mentioned. The part should be washed with soap and water, and rubbed till the blood is introduced into the most delicate branches of the erectile tissue; the skin is then made tight, and covered with colour similar to the natural colour of the skin, which is formed of white lead and carmine. Three needles, sunk into a cork pad so that their points project, are then thrust into the skin, and their points from time to time dipped in the paint. In extensive spots we must proceed gradually, so as not to produce too great swelling. The most difficult part is the choice of colour corresponding to that of the skin.

1520. The veins are, on account of the weakness of their membranes, subject to a great degree of extensibility, and then form swellings which are called *Vein-knots* (*Varices*, Lat.; *Blutaderknoten*, *Krampfadern*, Germ.; *Varices*, Fr.)

1521. Expansion of the veins generally takes place very slowly, and at first is not accompanied with any inconvenience; it gradually increases, the veins describe, in their course, larger curves, form unequal, defined, bluish or blackish prominences, which diminish on the application of pressure, but quickly return on its withdrawal, and cause a sensation of weight, and often severe pain in the part where it is situated. Varicose veins, by their lying together, often produce large swellings and *œdema* of the whole part: the coats of the veins thicken, adhere to the neighbouring parts; the skin covering them inflames, abscesses form, ulcerations also take place in the skin, and cellular tissue, (varicose ulcers,) which are closely connected with this varicose state, and so long as it continues cannot readily be induced to heal (1). Often by bursting of the vein considerable bleeding ensues; and sometimes the blood is poured into the cellular tissue by tearing of the vein. Often the blood coagulates in the expanded vessel, and the knots thereby produced are hard and incompressible (2). For the most part only the superficial, more rarely the deep-seated veins, in many cases not only the venous trunks, but also the minute branches, sometimes they alone, are expanded, and considerable swellings arise here and there.

[(1) **Brodie** says:—"For the most part, the effect of inflammation of a varicose cluster is not to produce either abscess or ulcer. It is very remarkable that the blood in inflamed varicose veins coagulates; and they become choked up with the coagulum. There seems to be something in an inflamed vein that is unfavourable to the fluidity of the blood which it contains. You observe this not only when varicose veins of the leg are inflamed, but when the veins are inflamed under other circumstances, as in a case of piles. A patient comes to you with an external pile, which is large and very tender—it is inflamed. At first it contains fluid blood, but in a day or two it becomes filled with solid matter, and if you slit it open you find a solid lump of dark-coloured fibrine. If you slit open an inflamed varicose cluster in the leg, under these circumstances, you will also find that the cavity is filled up in like manner with coagulated blood. * * * The coagulum fills up the vein, and the vein becomes obliterated. Other varicose clusters may appear afterwards, but this one is cured. * * *

By degrees the inflammation subsides; the coagulum becomes gradually absorbed; as the absorption proceeds, the sides of the vein approximate, and it assumes the appearance of a narrow cord. In old cases of varicose veins, you will frequently find the skin become affected with a chronic inflammation; that is, it will look red, and be very irritable and tender. Sometimes the cuticle is, as it were abraded, and an ichorous discharge takes place from the red *cutis*. Occasionally the whole of the skin of the leg is in this condition. In other cases there is a chronic inflammation of the cellular membrane. There is an effusion of serum into it and the limb becomes œdamatous. * * * These inflammations are analogous to what we meet with in other cases of venous congestion. But in some instances you find inflammation taking place of a different kind in the cellular membrane, immediately surrounding the varicose cluster. The cellular membrane becomes infiltrated with coagulated lymph, so that the varicose cluster is, as it were, imbedded in a mass of solid substance. At first you would suppose that these veins are obliterated, but they are not so. The lymph which has been deposited becomes organized, and the coats of the vessel are thickened, but they remain pervious nevertheless, containing fluid blood, which may be perceived with the finger, flowing freely through the gristly mass. Where there is this deposit of lymph in the cellular membrane round the vein, the skin becomes inflamed near it, and this may give rise to a troublesome ulcer. The more usual history of a varicose ulcer, however, is as follows:—the skin is distended at some point, and a scab forms upon it. When the scab comes off there is an ulcer, and the ulcer spreads. The varicose ulcer in most instances begins about the inner ankle, but it may occur in other parts of the leg. * * * Such ulcers are inclined to assume an oval form, the long diameter of the oval extending in the course of the vein upwards and downwards. They are generally nearly on a level with the surrounding skin. The surface of them is dark-coloured, when the patient is erect, and when the small veins are filled with blood; but when the patient lies down it becomes florid; the change taking place very speedily from dark to florid and from florid to dark. The skin and the margin of the ulcer are generally of a dingy-red colour and partly deprived of the cuticle, so that it is often difficult to say where the latter terminates and the ulcer begins. Varicose ulcers are generally very

288 VARIX.

They are generally nearly on a level with the surrounding skin. The surface of them is dark-coloured, when the patient is erect, and when the small veins are filled with blood; but when the patient lies down it becomes florid; the change taking place very speedily from dark to

rated, as not only to prevent all circulation of blood through this part of the vein, but even in a great measure to prevent the admission of air by inflation. * * * The blood being prevented from passing through the *vena cava inferior,* flowed into the lumbar veins, enlarging them gradually, as that vein became contracted, till they were of sufficient size to receive the whole blood which returns by the *vena cava.* * * * The enlarged veins were in some places thrown into *varices,* as must naturally take place under the circumstances we have mentioned. (pp. 127, 28.)

Brodie (*a*) says he has seen varicose veins of the fore-arm to a considerable extent. There had been inflammation of the median-cephalic and cephalic veins. These had become obliterated, and in consequence of their obliteration, the blood did not easily return from the fore-arm, so that the veins became varicose." (p. 159.)

Scarpa (*b*) observes:—"The celebrated Mr. **Cline** having found in the body of a man, the *inferior vena cava* obliterated a little above its bifurcation, in consequence of a steatomatous tumour, which had formed in the cellular tissue behind the *peritonæum,* and which occupied a part of the *pelvis* and lumbar region, remarked that the epigastric veins were become as large as the little finger, and that the superficial veins of the *abdomen,* as well as the lumbar, and those of the internal cavity of the *abdomen,* were in a similar manner very much dilated; the internal mammary vein likewise greatly enlarged, and also the epigastric, with which it anastamosed, opened, as usual, into the *superior cava,* near to the origin of the subclavian veins; by which circumstance the venous blood of the lower extremities was poured into the *superior cava,* by means of the mammary vein, and into the *inferior cava* by the lumbar veins above the compression caused by the steatomatous tumour." (p. 21, *note.*)

Brodie relates the case of "a man who had varicose veins all down the right arm, and to a considerable extent down the right side of the chest. He had difficulty of breathing, and cough. One day he felt as if he had received a blow on one side of the chest, and immediately a large abscess presented itself externally, as big as an orange, which had evidently made its way from the inside of the chest through one of the intercostal spaces. Immediately upon the appearance of this swelling, the varicose veins disappeared. The man died, and on *examining* the body after death, it was found that there was disease in the bronchial glands; suppuration had taken place in them, and a large abscess had been confined in the inside of the chest, which pressed on the right subclavian vein, and this caused the blood to stagnate in the veins in which it had its origin, and which had in consequence become varicose." In another case, "the superficial veins of the chest and upper extremities were extensively varicose. * * * On *examining* the body, a large medullary tumour was discovered within the chest, which by its pressure on the lower part of the *trachea,* and on the junction of the two subclavian veins, had obstructed at once the entrance of the air into the lungs, and the return of the blood to the *superior vena cava.*" (pp. 159, 160.)

(2) Generally speaking, the superficial veins are most prone to become varicose, and specially those of the lower limbs. **Hodgson** says:—"The only instance of *varix,* in the upper arm, with which he was acquainted, is mentioned by **Petit** (*c*); it was situated at the bend of the arm, and the patient was so fat that no other vein could be found for the purpose of venesection, which operation **Petit** repeatedly performed by puncturing this *varix.*" (p. 539.)

Brodie's cases just mentioned are also examples, though from different cause.

Velpeau says he has seen in two persons the arms, fore-arms, and hands covered with varicose swellings; also a mass of *varices* as big as the fist, between the angle of the jaw and the right clavicle, in a young man; a *varix* as large as the thumb under the edge of the orbit in a girl; and a pretty large one, in a man, upon the course of the sagittal suture, which seemed to come from the longitudinal sinus. And he mentions another, as big as the thumb, beneath the tongue. (p. 420.)

But the deep veins also occasionally are so affected, as in the instances just cited even within the great cavities of the trunk. I have also very recently seen in St. Thomas's Hospital, a varicose enlargement of the femoral vein, immediately below **Poupart**'s ligament, as big as half a pigeon's egg, and in the seat of femoral rupture, for which it might have been easily mistaken. **Hodgson** also says:—"**Mr. Cline** described in his lectures the case of a woman who had a large pulsating tumour in her neck, which burst, and proved fatal by hæmorrhage. A sac proceeded from the internal jugular vein. The carotid artery was lodged in a groove at the posterior part of this sac." (p. 539.) I have no doubt that this is the brief history of a preparation in the Museum at St. Thomas's, which precisely corresponds with the account.—J. F. S.]

(*a*) Above cited.

(*b*) On Aneurism (Translation.)

(*c*) Traité des Maladies Chirurg., vol. ii. p. 49.

1523. The *cure* of varix first requires the removal of the cause which hinders the circulation in the veins; and this done, it frequently disappears of itself. Obstructions in the bowels must be got rid of, the mode of living properly regulated, continual standing, and the like, forbidden. The most proper remedy, if after the removal of the causes the knots do not subside, or if they depend on local weakness, is the suitable compression of the whole part with bandages, the effect of which is assisted by the employment at the same time of strengthening contracting remedies. A radical cure thereby is rarely effected, for when the compression is removed, the swellings of the veins, *œdema* and varicose ulcers return.

[BRODIE says:—"In many cases where the disease is limited, you may apply merely a partial bandage of adhesive plaster, which will answer the purpose perfectly, giving the patient scarcely any inconvenience. There being, for example, only two or three varicose clusters of small size, you need not trouble the patient with a complete bandage for the whole leg. * * * Having marked the place, (whilst the patient stands erect,) let him recline with the foot raised so that it may be the most elevated part of the whole body. Then, the *varix* having been thus completely emptied, apply one of the pieces of adhesive plaster (three or four inches long, and an inch or an inch and a half wide) across the varicose vessels, and afterwards apply the others in the same manner, drawing up the skin under them, and taking care that the plaster is not thrown into folds. The plasters being applied in this manner, and being strained on the skin beneath, prevent the vein from becoming distended when the patient stands erect." (p. 169.) If the skin be irritated by the resin in the adhesive plaster, he recommends instead *emp. thur. comp.* with a little soap cerate, or soap plaster spread on *amadou*. "In those cases, however, in which the veins of the leg are extensively varicose, this partial compression will not be sufficient, and you must apply a bandage for the whole leg." (p. 170.) Calico, flannel, or stocking-web roller; the Indian rubber web confines too much heat, and does not, in most instances, afford sufficient support to the weak vessels. Laced stockings, either of nankeen, Indian rubber cloth, or spiral wire are sometimes used, but the latter two are objectionable, on account of the heat.

If the varicose veins become inflamed, the patient should be kept in bed in the recumbent posture, have cold lotions applied, and his bowels freely opened; and occasionally it may be necessary to employ leeches, on the use of which BRODIE gives the following very pertinent advice:—"Do not apply them immediately over the veins; they should be applied higher up on the leg, on the sound skin. The bite of a leech over an inflamed vein will give the patient a good deal of pain, and the little wound will be difficult to heal. If you apply the leeches on the sound skin on the thigh, or the upper part of the leg, you will relieve the varicose veins just as much as if you had applied them on the veins themselves, without giving the patient pain at the time, or trouble afterwards." (p. 173.)]

1524. In order to effect a *radical cure* of varices by closure with a clot of blood, and by obliteration of the vein, various remedies have from the earliest times been proposed. *First*, puncture; *second*, incision; *third*, extirpation; *fourth*, tying; *fifth*, cutting through; *sixth*, application of caustic; *seventh*, piercing with needles or threads; *eighth*, lateral compression of the veins.

According to GOTTSCHALK (*a*), the destruction of a vein never produces a radical cure; on the contrary, the especial cause of varicosity, to wit a slow circulation in the veins, is further increased; hence there results from tying a venous trunk *œdema* of the limb, and aggravation of the disease, in addition to the danger of tying the vein. Support of all the veins by simultaneous compression is the true mode of cure, and there is nothing more proper for this than a paste roller. A moist roller is first applied, and then smeared with paste, and over it a second paste roller. The moisture cools the limb pleasantly, and the regular pressure removes all the weight depending on expansion of the veins.

1525. *Puncture of the varix* with a lancet (anciently proposed by HIPPOCRATES) must especially be employed in varices largely filled with

---

(*a*) OPPENHEIM's Zeitschrift für die gesammte Medicin, vol. xxii. pt. ii.

coagulated blood, as well also as in those which are very painful, inflamed and much expanded; and, after the removal of the blood, pressure, together with cold applications and the horizontal posture are to be employed.

1526. In cases of larger size and greater extent, the skin and the vein must be *cut into*, by an incision two inches long, upon the largest knot, the escaping blood kept back with the finger, the cavity of the vein plugged with sponge or lint introduced into it, and the bleeding stanched by the application of compresses and circular bandages. If the varicose expansion be only on the leg, one cut is sufficient; if it extend to the middle of the thigh, one cut is to be made above the ankle, a second close above the knee, and if the whole thigh be affected, a third cut is to be made at equal distance. The limb is then to be bandaged, and cold applications to it used for some days. Inflammation takes place in the vein which so spreads from the principal to the other varix, that a greater degree of plasticity arises in them, and the neighbouring varices disappear (*a*).

1527. In some very prominent knots, or even in swellings formed by the agglomeration of various veins, *extirpation*, (*cirsotomia*,) originally proposed by Celsus, has been practised. In the separate knots, the skin, if movable, should be cut through in a single fold, so that the cut may reach from above to below, over the knot, which is then to be raised with the hook, separated, and cut off above and below. If the skin be adherent, it must be taken away as well as the knot. In the same manner the large swellings are to be treated, and the divided vein tied at its upper and lower end; or, if the position permit it, the bleeding is to be stanched by pressure (*b*).

1528. *Tying* (proposed anciently by Aetius and Paulus Ægineta) is to be performed in varix of the lower extremity, on the principal trunk of the saphenous vein, above the swollen part, which is to be laid bare by a suitable cut through the skin, freed from cellular tissue, and the ligature carried round it with a probe; after which, pressure is to be kept up in the horizontal posture (*c*). Ricord (*d*) removes the subcutaneous connexion of the vein, lifts up the vein in a fold of the skin, and thrusts a suture needle, armed with a double thread, through the skin behind the vein, then lets go the vein, without leaving hold of the skin, and carries the needle back through the same holes reversed above the vein, so that the vessel is caught in a subcutaneous loop, both ends of which being held together at the same wound in the skin, are tied on a piece of elastic bougie as in the quill suture. In a similar way, but with two loops, the subcutaneous tying may be performed, according to Tavignot's method. (*par.* 1432.)

[The practice of tying the saphenous vein was revived by Sir Everard Home, for varicose veins of the leg, either with or without ulcers; and he stated (*e*), "that in the course of a week after the operation, the veins in general were very much diminished in size; and in all the cases the ulcers put on a much more healthy appearance in less than three days after the operation; and from that time, where no circumstance occurred to prevent it, went on healing like ulcers in healthy parts." (p. 330.) It, however,

happened after this statement, that several patients died from inflammation of the vein following the ligature; and I recollect being present at an operation of this kind, after which the patient became extremely ill and delirious; and, though she recovered of the operation, lost her senses, and was obliged to be placed in a madhouse. These results put a stop to this dangerous practice, vaunted as it had been by Home; and there are, I apprehend, few persons who would now venture on performing it.—J. F. S.]

1529. Solera practised *cutting through the vein above and below the knot*, above the knee and low on the leg; he made a longitudinal cut by the side of the vein, cut through the vein, and prevented its union by the introduction of lint. Brodie (*a*) makes the subcutaneous division of the vein, but he thrusts a narrow, very pointed, slightly-curved bistoury, flat on the side of the vein, between it and the skin, and, in withdrawing it, cuts through the vein without wounding the skin. The bleeding is stanched by pressure.

[In reference to the sub-cutaneous division of varicose veins, Brodie observes:— "Although there may be danger from operations on the *vena saphena*, we have no right to expect danger from operations on its smaller branches" (p. 188); and it was upon these he formerly operated. "With my present experience," he, however, observes, "it really appears to me that, in ordinary cases, it is not worth the patient's while to submit to it, as I always observed that, if I cured one cluster, two smaller ones appeared, one on each side, and that, ultimately, I left the patient no better than I found him. The operation, however, is proper where there is a varicose cluster much distended, and liable to burst and bleed. Here you may actually save the patient's life by having recourse to it; and you may do so without considering whether fresh clusters are or are not likely to form afterwards." (pp. 189, 90.)]

1530. The *application of the actual cautery* (according to Celsus, upon the knot laid bare by a cut through the skin) and the *destruction of the skin and the knot with caustic potash* (Paré, Brodie) have been given up on account of the obstinate ulcers to which they gave rise (1); but the employment of caustic potash is again recommended by Bonnet (*b*) and Laugier (*c*). Bonnet at the same time employs the introduction of needles after Davat's method, and the latter applied the caustic upon the vein, after laying it bare with a cut through the skin. von Froriep overlays very large expanded veins of the lower extremity with compresses, moistened with concentrated, not smoking nitric acid, till the skin becomes erysipelatous, and the swelling firm and painful, and repeats it, after the subsidence of these symptoms, till the cure.

[(1) Mayo (*d*) has also recommended the use of caustic potash, or a caustic paste on the sub-cutaneous venous trunks of the leg in cases of *varix*. "The vein," he says, "is often tender during several days, for the extent of three or four inches above the place at which the caustic is applied. The obstructed part does not exceed more than half an inch to an inch in length. I have never known acute *phlebitis* supervene in employing this practice." (p. 433.) Brodie, however, is now entirely opposed to it; he says:—"The application of the caustic potash was very painful; the slough took a long time to separate; the sore took a long time to heal; and where one cluster was cured, other clusters appeared. Altogether it was a very tedious process, and my own experience does not lead me to recommend it." (p. 187.)]

1531. The *introduction of needles through the walls of a vein* produces either only slight irritation of the vein, and the formation of a clot, which fills its area, and finally causes its obliteration; or, with a less degree of irritation of the opposite points of the internal coat of the vein, and their simultaneous contact, produces its obliteration. In the *first* proceeding

(*d*) Outlines of Human Pathology.

a pin (an insect-pin) is to be carried transversely *through* the vein, and left there for from two to six days with rest, and corresponding dietetic treatment of the patient. On the second day swelling around the pin begins, which is caused partially by the clot formed in the vein, partially by the slight inflammatory process set up in, and around it. The swelling increases on the following days, becomes at the wound, more rarely throughout its whole extent, of a pale rosy-red colour, and at the same time the vessel, as well as its neighbourhood, without pain on pressure, feels more compact. The earlier this appearance sets in, the sooner may the pin be removed. With small veins one pin is sufficient; but in the larger it is better to introduce two or three, in which case the one brings the front, the other the hind wall of the vessel nearer together, and the third is thrust through the middle of the vein. Experience is strongly in favour of the symptoms ensuing, and of the results arising from this mode of treatment (*a*). In the *second* proceeding, a pin is to be thrust transversely *under* the vein, which is to be raised up by it, so that a second pin may be thrust *through it twice*, in the longitudinal direction. With this object a second pin generally straight or curved, round or flattened, is introduced through the skin and vein, about a line below the place where the transverse pin cuts the axis of the vessels, carried upwards beneath that pin, and thrust from within outwards through the vein and skin—the two pins, forming a cross, are to be surrounded with a thread. One pin may be also thrust transversely through the skin and vein, and a thread twisted round it, like a figure of ∞. The pin is to be left till it have excited inflammation (about five days.) The little fistulous wound soon heals. This mode of treatment should be preferred before all the rest, on account of its slightness, of its less pain and danger, and the certainty of the cure (*b*). Experience, however, shows that wide and deep-spreading phlegmonous inflammation, with fever, redness of the tongue, sooty colour of the teeth, irritation of the mucous membrane of the stomach, swelling of the inguinal glands, extensive suppuration, and even death may ensue from this practice (*c*). According to Franc (*d*), the pin should be thrust through the skin near the vein, carried behind it, thrust out at the other side, and a thread wound around it. Two days are sufficient to produce complete obliteration of the vein (1). Fricke (*e*) introduces, with a moderately strong needle, one, and, in great varicosity, several threads dipped in oil through the vein, and ties the ends upon the skin in a bow. In from twenty-four to thirty-six hours the threads are to be removed, the patient kept quiet, without any dressing, and, on the appearance of inflammation, cold water or lead wash are to be applied.

[(1) Velpeau (*f*) says, that he "never saw, in more than one hundred cases in which he had performed his operation, any troublesome symptom; a slightly spreading external *phlebitis*, some little phlegmonous swellings, and small abscesses, were nearly all the consequences. Often pleasing myself," says he, "with my continual success, you may

judge what fear I had of it coming to an end. Unfortunately, at last it came." A patient was operated on by him on *April* 4, 1839, two of the pins were removed on the *sixth*, and the other two, with the ligatures, on the following day, the tied parts being scarred, and the patient free from pain. On the *eleventh* night, however, he was attacked with intermitting shiverings accompanied with nausea and vomiting; and on the following morning the leg was red and swollen, which extended next day up the thigh, and where the ligatures had been applied the skin assumed a violet-colour, and livid spots appeared on different parts of the body; he became delirious, had continual tremors, and weak quick pulse. On the *fourteenth* day the face had become purple, the lips dry, and he was very comatose: large and distinct spots appeared on the inside of the arms, and the hands were swollen and bluish: the whole of the limb which had been operated on was enormously swollen; the extremities became cold, and he died the same morning. The only important points in the *examination* were the fluidity of the blood, and the enormous distension of the *vena cava*; incipient ulceration in the intestines: the vein which had been tied had not been perfectly obliterated. (pp. 442, 43).]

1532. *Lateral compression of the vein* (according to Breschet's practice in *Varicocele*) has been performed by Sanson (*a*) by means of forceps, between which a pair of metal plates, fifteen lines long, covered with leather, which compressed the vein, raised up in a fold of skin sufficiently to prevent the blood circulating through it. The forceps are to be frequently applied at different places, so that no slough should be formed. A plug of blood is thus produced, which stops up the vein.

1533. In reviewing these different modes of treatment for the radical cure of *varix*, it must be remembered that in all those accompanied with wound of the vein, there is danger of venous inflammation arising, which often spreads widely and causes death. This is the more important, as persons who are subject to varix have, for the most part, accompanying gouty or rheumatic affections, stoppage, and fulness in the belly, and extensive alterations in the venous system at the same time, whence they are the more disposed to such inflammations; so that it must not be overlooked that, on account of the causal relations of *varix* to such general diseased conditions, it often belongs to the relative well-being of the patient, and that after its removal other symptoms set in, or expansions in other parts of the venous system occur. Such radical cure of *varix* must therefore never be undertaken without careful review of the patient's general condition, and never without important reason, and pressing demand. In old persons it has never any benefit. Puncture is least dangerous; but, in regard to its result, a radical cure, very uncertain. Tying and incision most frequently set up dangerous inflammation; less so do extirpation and the introduction of threads. But even in the latter seemingly trifling proceeding, inflammation of a very severe degree may ensue, though less after the simple introduction of the needle or thread, (Kuh, Fricke,) than in tying the vein at the same time, (Davat, Franc, and others,) in which the circulation through it is entirely arrested. In this respect the simple compression of the vein, after Sanson's plan, deserves especial notice, if further observation should prove the certain closure of the vein thereby.

Fritschi, J., Ueber die Radicalkur der Phlebectasia spermatica interna oder sogenn. Varicocele, u. s. w. Freiburg, 1839.

1534. *Varicocele* or *Cirsocele* is a varicose expansion of the veins of the spermatic cord, and in a more advanced state of those also of the *epididymis* and testicle. The disease always commences in the spermatic cord, and generally makes itself known by a heavy, often smart pain, which from time to time darts to the testicle and loins; the ailment, however, frequently develops itself without any inconvenience. An irregular swelling, consisting of several threads, is felt along the course of the spermatic cord, which diminishes on slight compression. In proportion as the swelling gradually increases, it approaches nearer the testicle, which enlarges, and becomes heavier; by degrees the varicose condition extends to the *epididymis,* and thence to the testicle itself, which is loosened into a soft, doughy mass, and presents only a convolution of expanded vessels, probably simultaneous thickening of their walls, and of the cellular tissue connecting them. The purse also is expanded, and the patient feels a troublesome or painful weight in the testicle, which sensation extends to the loins, especially when it has existed a long time. The characteristic signs of *varicocele* are the ready disappearance of the swelling on compression, its quick reappearance when the pressure is withdrawn, as well as its increase on long-continued standing. As these appearances belong to ruptures, and as in a large *varicocele* the swelling enters the abdominal ring, by which it is enclosed, and its condition, when touched, has resemblance to that of omental rupture, the history of the disease, and the characters already described (*par.* 1200) must give the *diagnosis.*

The words *cirsocele* and *varicocele* are used with different significations. Many writers apply the former only to a simple swelling of the superficial veins of the purse; but the second to a swelling of the spermatic veins. Some employ *varicocele* in this double acceptation, and *cirscocele* as a swelling of the vessels of the *epididymis* and testicle: again, others consider both designations as of similar import.

According to Breschet (*a*) *spermatocele* is a swelling of the spermatic cord, and especially of the *epididymis,* depending on retention of the *semen.* It begins with a sensation of pressure, distension, and more or less severe pain. If the *semen* be not voided by pollution or by connexion, inflammation, bursting of the swelling, and actual fistula ensues, which is characterized by the escape of the *semen* (1). This affection of the *epididymis* is especially observed in *gonorrhœa,* and the swelling of the testicle ensuing in proportion to the decrease and entire cessation of the *gonorrhœa,* which always begins in the *epididymis,* depends on the retention of the *semen.* In this spermatocele, connexion, moderate living, avoidance of exciting the imagination, cold washes to the generative organs, and, in inflammation, the application of leeches are to be recommended. In fistula nothing can be done directly.

[(1) Spermatocele is often a sore nuisance to young people; the testicle become so exceedingly tender that the mere pressure of the dress upon it causes great pain. It is not generally accompanied, at least in the cases I have seen, with much swelling and I have never seen it followed by suppuration, as Breschet states. But I have known it

---

(*a*) Observations et Réflexions sur la Fistule spermatique ou Spermatocèle; in Journal général de Médecine, 1826, June, p. 348.

recur very frequently, at intervals of two or three months, for as many years, between sixteen and two or three and twenty. I do not believe it will have usually the results stated; but it is a most troublesome and annoying complaint, compelling the patient to keep himself completely at rest, and is not very easily controlable. Keeping the bowels free, and avoiding excitement of all kinds, bodily or mental, with a cool dressing, and supporting the testicles with a suspensory bandage, is almost all that can be done; and that not of much benefit. Usually after a time it is outgrown, and the disposition to it ceases.—J. F. S.]

1535. The causes of varicocele are various, though in some cases often not at all determinable. For the most part it depends on weakness of the spermatic veins, produced by great congestion, in consequence of venereal excesses, onanism, or from long-continued libidinous appetite, or after previous inflammation of the testicle, from obstructed return of the blood in persons of sedentary habits, in swellings and costiveness of the bowels, from a truss pressing the spermatic cord, from particular employments, and so on. The disease occurs more frequently on the left than on the right side, the ground of which is to be sought for in various causes (1). Sometimes it is accompanied with hæmorrhoidal inconvenience. The disease is most commonly noticed in young persons, from fifteen to thirty years of age, rarely in older people. In many cases, however, the ætiology of this disease is quite obscure, and it is indeterminable what share the above-mentioned causes have on its origin. The complaint often remains in a slight degree stationary, although, on account of the mode of living and employment of the patient, its increase is on every ground to be feared (*a*).

(1) Many derive this disease from pressure of the sigmoid flexure of the *colon* on the vessels of the spermatic cord. MORGAGNI and A. COOPER place the cause in the entrance of the spermatic vein of the right side into the *vena cava ascendens*, in an almost parallel direction with that vessel, whereby its emptying is more readily effected; whilst the vein on the left side terminating in the emulgent vein, the circulation produces an obstacle, as the two streams do not take the same direction. The length of the veins of the spermatic cord, on the left side, has also been charged with it, as well as the narrowing of the mouth of the left inguinal canal, in consequence of the contraction of the abdominal muscles, in the exertion of raising weights, on account of the bending over to the right side (LENOIR.)

1536. If the disease be left to enlarge, it changes the structure of the testicle by overspreading it, rendering it useless for its function, or atrophic: by the enlargement of the swelling are produced swellings of the veins of the purse, inconvenience from its weight, and not unfrequently considerable pain, especially on long-continued standing, or any overexertion, and even the impossibility of walking without a suspender. In general there is also a greater secretion of the scrotal skin. Where a quick course of the disease, with violent pain and speedy wasting of the testicle have been observed, (POTT, A. COOPER,) it appears to depend less on the varicocele than on another and indeed traumatic influence.

1537. The *treatment* of varicocele must principally depend on its cause, and when this is known, it must be removed according to the general rules laid down. In a trifling degree of the disease, the purse may be supported by means of a well-fitting suspendor; and by the repeated use, during the day, of cold astringent applications of lead wash, solution of alum, aromatic decoctions, frequent washings with these remedies, or with cold water and spirits of wine, or with *liq. mineralis* HOFFM., naphtha, and so on; even blisters may be applied to the purse to increase the contractility of the part. The patient must at the same time

---

(*a*) DELPECH, Précis élémentaire, vol. iii. p. 266.

avoid all exertion, constant standing, and walking; and especially he must properly regulate his living. In most cases, however, the inconvenience of the patient is only lessened, and a check given to the progress of the disease.

1538. In the more advanced state of varicocele, if it cause considerable inconvenience or be connected with rupture, various modes of treatment have been proposed with a view to the radical cure, as extirpation of the varicose vessels, tying all (1), or a single bundle of the swollen veins (2), tying the spermatic artery (3), carrying through threads or needles, or a simultaneous surrounding of the latter with threads (4), excision of a part of the purse or its inclusion in a ring (5), the ensheathing of the skin of the purse (6), and the continuance of pressure by means of a compressor or a pair of forceps (7).

(1) According to Celsus the superficial veins were cauterized with a pointed iron, and the whole bundle of deep veins tied and extirpated. In the same way have Paré, Heister, Petit, Cumano, Key, and others, proceeded with some modification, in which they have only removed the veins, or even the testicle itself.

(2) Charles Bell considered the separate tying of one or more venous strings sufficient. The veins are to be laid bare by a longitudinal cut through the skin and general scrotal covering, one of the largest venous strings grasped with the fingers, separated and tied with a thread. When this disease is very large, two and even three strings must be tied; and the wound closed. The ligatures separate in a few days.

Delpech (*a*) divides the skin by a cut of two inches long, parallel to the spermatic cord, cuts through the *m. cremaster* and sheath with the forceps and bistoury, raises one vein from the rest, isolates it, passes under each a piece of thick soft German tinder, and then puts a single ligature on the latter. The ligature is only to be drawn so as merely to bring the walls of the vein together, and prevent the flow of blood through it; whereupon great swelling of the varicose vein ensues. The wound is to be lightly filled with lint and covered with a softening poultice. The ligature is to be removed on the third day. Delpech has noticed, after the performance of this operation, the restoration of the function of the testicle.

Tavignot's subcutaneous ligature in the way already mentioned. (*par.* 1432.)

(3) Maunoir, (*b*), Brown (*c*), Amussat (*d*) and Jameson (*e*), have tied the spermatic artery successfully, but Graefe (*f*) without success. According to Maunoir, the cut should be made half an inch long, below the abdominal ring in the course of the cord, its sheath opened, the artery separated, a double ligature applied, and the vessel divided between them. If the varicocele exist in such degree that simultaneous loosening of the spermatic cord and testicle expand the *scrotum* to a large swelling, this proceeding is more difficult, and it would be better to make, close above the external abdominal ring, a cut two inches long, obliquely upwards and outwards, to cut through the outer walls of the inguinal canal, to open the sheath of the exposed spermatic cord with a shallow incision, and carefully to separate the artery. In this case it must not be overlooked that the spermatic artery also divides below the external ring (*g*).

(4) According to Fricke a part of the purse should be grasped with the left hand, so that one of the expanded veins may be found between the fingers, upon which with a common needle the skin and vein are to be pierced obliquely, and a thread introduced which is to be tied upon the skin. This operation, which may be repeated on one or two other veins, is easily performed and little painful. The purse should be kept horizontal and supported on a pillow. If, on the next day, redness of the skin and sensibility of the testicle occur, the thread is to be withdrawn. The swelling gradually subsides, and the veins are converted into solid strings, free from pain.

According to Kuh (*h*) every single vein of the *plexus*, on both sides of the purse, is to be grasped with the fingers and perforated with a needle, each needle to be ensheathed in a proper cork, and the purse supported with compresses or a suspender.

(*f*) Klinischer Jahresbericht, 1822.

(*g*) Dietrich, above cited, p. 448.

(*h*) Above cited, p. 58.

According to Davat and Franc (*a*), the varicose veins should be separated from the *vas deferens*, and one or two needles thrust between them ; a waxed thread is to be twisted several times round such needles, and tied fast, by which the vein is constricted and obliterated. Franc believes that two days, and even a shorter period, is sufficient to produce complete obliteration of the vein. Raynaud's practice (*b*) agrees with this, but that he applies a linen cylinder on the skin, upon which he ties the threads together ; by tightly tying, he divides the spermatic cord till the skin alone remains undivided, which, after the ligature has been drawn out, is divided upon a director, and the superficial wound heals quickly afterwards.

(5) Wormald (*c*) passed the lower part of the purse through a soft, wide silver ring, an inch in diameter, and covered with leather, whilst the patient reclined, and the veins were empty, and fastened it so tightly together that the parts could not escape. This was done every morning, whereby inconvenience was avoided. A. Cooper (*d*) objects to this proceeding, and recommends cutting off a sufficiently large flap of skin from the purse, after which the suture is to be so applied that the lower flaps of the wound should support the testicle like a suspender. By this means the varicocele is diminished, though not removed, but all inconvenience is got rid of.

(6) In a similar manner the ensheathing and shortening of the purse, proposed by Lehmann (*e*), acts. The whole of the front of the purse is thrust up with the fore-finger of the left hand, so high beneath the skin of the belly, till the bottom of the purse is brought above the horizontal branch of the share-bone, and the testicle lies pretty close to the belly. Gerdy's rupture-needle, armed with a double thread, is then introduced into the bottom of the ensheathed canal, the purse, and the over-lying skin of the belly, penetrated with its point, so that the eye with the threads may project some lines. With the assistance of a pin, the end of one thread is to be freed from the eye and the needle being drawn back, is then thrust through again in the same w[illegible] half an inch deeper, and the other end of the thread pulled out. The ensheathed skin is drawn with the thread loop so close to the belly, that the testicle lies hard by it. The two ends of one thread are then tied upon a wooden cylinder, as big as a crow quill, about an inch and a half long, and covered with sticking plaster; and afterwards the other.

(7) Breschet (*f*) has proposed a simple and certain mode for employing compressors, both for the swollen veins of the purse, and also for those of the spermatic cord ; and from his practice are, to a certain extent, those of a recent date derived.

Compare also Landouzy, above cited.—Rognetta ; in Bulletin de Thérapeutie, vol. vii. pt. i.

1539. Of these various modes of treatment for the radical cure of varicocele, both according to my own and others' experience, that proposed by Breschet as regards its easy employment, its applicability to the different stages of the disease, its certainty, and its freedom from danger, is to be esteemed the most proper and the most preferable. Extirpation of the testicle, and tying the whole bundle of veins, can bear no comparison with it. Tying the separate veins as proposed by Bell, has not been supported either by others' or by my own experience; and Bell himself subsequently did not advise it (*g*). Tying the spermatic artery is very difficult, often scarcely possible, on account of its intimate connexion with the other tissues of the cord, without injuring them, and on account of the variety of its ramifications uncertain in its result. Piercing the veins with needles or threads often risks the danger of inflammation and has uncertain success. The introduction of one or several threads, or of a single thread below the bundle of veins, may also produce severe symptoms, is more tedious, more painful, and consequently less favourable than the practice of Breschet (*h*). The drawing into a ring, and cutting off flaps of the scrotal skin, are merely palliative.

1540. In order to include all the veins, in the operation after BRESCHET's method, the patient must walk about for some hours previously in summer, and in winter keep in a very warm bed, by which the veins are filled with blood. The purse is to be shaved, and the patient placed in front of the operator, who with his left hand grasps the right side of the purse, with the fore and middle finger behind, and the thumb in front, with its tip on the *septum*, whilst the two fingers support the testicle; the finger of the right hand is to be applied to the left side of the purse, so that the fingers may touch. The *vas deferens* is now to be found, which is easily done, in consequence of its position at the back of the cord, its string-like character, its equal thickness (that of a crow quill,) throughout, its hardness but elasticity, and by its peculiar painfulness when pressed. The *vas deferens* is now to be kept back with the finger and thumb against the *septum*, whilst the veins are drawn out from it with the same fingers of the right hand, in doing which especial care must be taken that not a single vein remain with the *vas deferens*. The *penis* is to be kept by an assistant lying upwards upon the belly, for the purpose of preserving on its under surface a sufficient length of skin, so as to prevent painful distension in the often recurring erections. The compressing forceps are then to be applied, first the upper as high as possible on the purse, though at sufficient distance from the *penis* as not to produce excoriation; the under one half an inch below the first, without, however, touching the testicle. The forceps are applied so across, that their arms grasp nearly the whole breadth of the left side of the purse, up to the *septum*, that the *vas deferens* remains unenclosed, and only the outer edge of the purse, to the breadth of from two to three lines, without the veins, is contained in the space between the arms of the forceps, and when they are closed is not squeezed. The arms of the forceps are now closed as tightly as possible with a screw, then by means of more violent pressure on a narrower space, a concealed plate on the upper arm is pushed forwards next the screw on the *septum*, and then that on the other arm screwed tight. The patient is then put to bed, the forceps kept against the belly by long strips of sticking plaster, and the purse supported with a cloth or with a ball of lint.

The same method serves for the left side, on which varicocele is most frequent, as that described for the right side, only the position of the hands is reversed.

For the above described compressing forceps, and their mode of application, see LANDOUZY, f. 1, 2, 3. BRESCHET's original forceps, their improvement by a movable plate. to effect pressure on three sides. I have employed the latter always with the best result.

1541. In the first hours after the operation, the patient feels a sharp pain in the purse and in the groin, but this subsides. Applications of lead-wash are to be made to the purse. When on the second or third day the forceps become loose, the plate is to be screwed tighter, which, if it be now only as at first properly done, does not cause much pain. When suppuration ensues, between the fifth and sixth days, the forceps are to be removed, and the remaining suppurating parts treated simply. If painful erections of the *penis* take place, which are most surely prevented by keeping the *penis* against the belly during the application of the forceps and subsequently, which I have never practised in my operations, small doses of camphor, with nitre, may be employed. The time necessary for the cure varies between three and six weeks. It is advisable, for some months after the cure, to wear a well-fitting suspender, and to use the cold bath and lead washes.

Syme, James, On the Diseases of the Rectum. Edinburgh, 1838. 8vo.

1542. *Hæmorrhoids* or *Piles* are varicose expansions of the veins in the lower part of the *rectum*, in which, by the collection of blood in these vessels, unnatural bags and sacs of different size, from that of a pea to that of a walnut, are produced. These swellings are commonly called *blind piles*, (*Hæmorrhoides cœcæ*,) to distinguish them from *flowing piles* (*Hæmorrhoides fluentes*, *apertæ*); they swell periodically, and again become lax, so that only the empty bags remain. If they have considerable size, they are called *sac piles* (*Hæmorrhoides saccatæ*); if small, *tubercular piles* (*Tubercula hæmorrhoidalia.*) The blood coagulates in the sacs often into a hard mass, so that a firm swelling is formed.

Only when these swellings are not very large, may they be formed simply by expansion of the walls of the veins; but if they be of greater size, the blood is poured out beneath the inner coat of the *rectum*, and expands it into a sac; hence the large size which the swellings often attain. It often happens that in cutting them off little or no bleeding occurs, and it is then distinctly perceived that they consist only of skin. They have also frequently a peculiar form, which *varix* cannot so easily acquire. This is proved, especially by **Kirby**'s careful observations, viz., that these excrescences do not consist of expanded veins, but of a sac-like lengthening of the thickened cellular tissue, surrounded with some veins, and covered with the integuments of the folded margin of the *anus*. The veins are branches of the internal *iliac*. In every case of internal piles the structure was the same, but the veins appeared wider, and were branches of the hæmorrhoidal vein. **Brodie**, on the contrary, asserts that in all cases he found the hæmorrhoidal knots only as expanded veins. In those of larger size more indeed than simple expansion of the veins is found, as there is effusion of lymph and thickening in the neighbourhood of the expanded vein.

1543. These swellings are often seated on the outer edge of the *anus*, or on the inside of the *rectum*, in the region of the *m. sphincter ani* or above it.

1544. The consequences resulting from piles are, *inflammation and suppuration*, *discharges of mucus* from the *rectum*, and *considerable bleeding*. If these swellings attain a large size, if, on going to stool, the piles within the *rectum* be protruded, they are often grasped by the aperture of the *anus*, swell considerably, are protuberant, and very painful. The pain often spreads over the whole belly, and the patient feels extremely painful *tenesmus*; the piles even become gangrenous. If they go on to suppuration, in which case syphilitic causes are mostly in play, suppuration may easily spread into the loose cellular tissue of the *rectum*, producing great destruction and fistula. Not unfrequently do these piles become converted into a hard fleshy mass, and even into cancer.

[Bushe has detailed an awful account of the symptoms of piles, most of which, however, result from the constitutional excitement they produce when inflamed, and are then occasionally very severe. The local symptoms are well described by him:—"A feeling of weight in the loins, hips, and groins; dull throbbing pain in the *rectum*, attended with a sense of increasing heat, *tenesmus*, mucous discharge, and occasional darting sensations, resembling those of electricity; itching of the *anus*, and finally painful, difficult, and frequent micturition."—(p. 146.)

"Frequently the loss of even a small quantity of blood," observes Bushe, "relieves the feeling of weight and tension in the *perinæum*, *rectum*, and lower part of the back, as well as any other disagreeable symptoms which may have existed. The amount of hæmorrhage, however, is not always in proportion to the severity of the symptoms denoting the loaded state of the hæmorrhoidal vessels—the quantity being sometimes very great, though not preceded by well-marked premonitory signs; while, in other cases, the discharge of blood is trifling, notwithstanding the fluxionary movement may have been well marked. Generally it ceases after a few days; yet not unfrequently it continues for months. In some instances it occurs but once in life; again, it may return in the course of a few weeks, months, or even years. Occasionally it assumes a periodical character, returning with the season or the month. The amount of blood lost varies; a drachm, an ounce, or even a pint may be discharged at a time, though it must be confessed, that the admixture of other fluids is apt to impose, upon the inexperienced, the belief that the loss of blood is much greater than it really is."—(pp. 146, 147.)]

1545. The *causes* of hæmorrhoids, besides predisposition, which is ascribed, to walking upright, to the difficult flow of the blood into the portal system, which is unprovided with valves, to hereditary habit, and to the flow of blood into the abdominal organs in advanced old age, are stoppages and costiveness of the intestines, much sitting, pressure of the pregnant womb, local irritation of the *rectum* from hard stools and continual riding, or of the neighbouring parts; for instance, of the bladder in urinary stone, and so on.

1546. The *treatment* of hæmorrhoids is various, according to the circumstances in which they are found. If they be inflamed, cooling remedies must be employed, cream of tartar with sulphur, leeches to the *perinæum*, cold applications; and if these cannot be borne, mild ointment and soothing fomentations. If the inflammation result from strangulation of the piles, their return must be attempted with the finger oiled, the patient being placed with his rump raised high, and all pressure removed; and if this be not easily effected, to empty them with a simple lancet cut. If they suppurate, the abscess must be soon opened to prevent burrowing of the pus, and if the ulceration depend on a syphilitic affection, the proper local and general remedies must be employed. If the bleeding from the hæmorrhoidal vessels be very severe, so that the patient is much weakened or his life endangered, rest and the horizontal position, best on a hard mattress, is to be recommended; internally, milfoil or other astringent remedies; externally, cold hip-baths, cold water with vinegar or spirits of wine, cold decoctions of astringent vegetables, or solution of alum and the like, may be employed as injections into the *rectum*, or as fomentations with a sponge. If these means be not of use, and the danger pressing, the bleeding must be stopped by plugging in the way described (*par.* 934.)

1547. If the piles produce by their size or hardening constant inconvenience, bloody, mucous, or purulent discharges exhausting the patient's powers, continual pain, and the like, if they be external to the *rectum*, or project at every time of going to stool, and prevent the discharge of the motions, their removal is indicated. It is, however, to be remembered, that after the destruction of the piles by the reflection of inflammation upon the other veins, their tone is raised, and thus in part the cause of the hæmorrhoids is removed. Where, however, they are a healthy habitual emptying, or when they have causal relations with incurable diseases, as, for example, *phthisis pulmonalis*, we must be cautious with their removal; it must either be not undertaken at all, or, at least, all the piles must not be removed at once.

1548. Extirpation of the hæmorrhoids has been proposed in three different ways. *First.* A ligature to be applied around the base of the whole swelling, and this gradually, and not at once, tightened, till the knots have fallen off (1). *Second.* The external skin of the pile is to be divided with a cut down to its base, and separated on both sides from the under-lying skin, which is to be cut off with scissors. The advantage of this practice is, that the remaining external skin covers the seat of the vein, and prevents the bleeding. *Third.* The pile is to be grasped with the forceps, drawn forwards and cut off with scissors in such way that some still remains on the base, by which the wound is partially covered. In external hæmorrhoids, the cut is to be made in the parts below the *sphincter*. The entire surface of the wound retracts into the *rectum*, and by the action of the *sphincter* is contracted, whence the danger of bleeding is very much diminished. If the wound be retracted above the *sphincter*, internal bleeding may take place. This practice is easy, and preferable to the others, as after the ligature there is often severe pain, inflammation, vomiting, retention of urine, and so on; as the division of the external, and the extraction of the internal skin, is always difficult, and in many cases, on account of their union, impossible. The large hæmorrhoids, also, are mostly formed by effusion of blood beneath the internal coat of the *rectum*.

(1) Rousseau, J. C. (*a*), passes a needle with two threads of *different colours*, from the *anus* outwards, through the swelling; then two-thirds of an inch farther back again from without to the *anus*, thus leaving between the stitches a loop of three or four inches long, and thus carries it around the whole swelling. He then cuts through the loop of the one colour to the outer, and that of the other on the inner side towards the *anus*. In this way is each part of the swelling surrounded with a ligature, which is to be drawn tight, and cut off short. If the swelling be large, the dead part, when it has become insensible, is to be removed, but not too close to the ligature. The ligatures usually fall off in seven or eight days.

Delpech (*b*) divided with a single cut the fibres of the *sphincter* muscle towards the *coccyx*, introduced a pessary, and let it be drawn with a string attached to it by an assistant, by which the swelling was reversed and cut off with a scalpel, but was then introduced, the string carried through the opening of another pessary. and tied upon a piece of wood so as to compress the *anus* between the two pessaries.

[Copeland and Brodie lay down as a general rule that internal piles should be removed by ligature. Bushe also prefers this mode, and says:—"I have now perperformed it, I am sure, upwards of a hundred times, and I have never seen a bad symptom follow it." (p. 187.) And Syme observes:—"I feel warranted, after very extensive employment of ligature, to state, that it may be used without the slightest risk of serious or alarming inconvenience." (p. 76.) It must not, however, be forgotten that serious inconvenience and fatal results will, occasionally, follow the application of

(*a*) Annual Medical Recorder, vol. ix. p. 282.
(*b*) Mémorial de la Clinique de Montpellier, 1830, Sept. p. 545.

the ligature to piles. **Petit** (*a*) mentions the case of a woman in whom, under very favourable circumstances, he tied three piles, which at first did not cause much pain; but, five hours after, she was attacked with violent colicky symptoms, for which she was bled four times without benefit; the ligatures were then removed, the symptoms yielded, and the patient recovered. In another case related by **Petit**, five ligatures were applied at once, inflammation and swelling of the belly, vomiting and hiccough ensued; the ligatures were removed, but the patient died. And he observes:—"I compare these symptoms with those, accompanying a rupture, in which a small portion of intestine is strangulated; if this kind of rupture be not speedily relieved, the patients die, sometimes in thirty or forty hours, of gangrenous inflammation of the whole belly, but particularly of the intestines; thus this patient died before the conclusion of the second day." (p. 125.) **Kirby** mentions two similar cases, one of which was scarcely saved, and the other died of *tetanus*. **Brodie** relates two fatal cases after ligature, in one of which the patient died, "in consequence of diffuse inflammation of the cellular membrane running up on the outside of the gut as high as the mesentery; but it was in a constitution broken down by long-continued hæmorrhage, and in whom any slight accident might have produced equally bad consequences." In the other case, the patient, "a week after the operation, and having been quite well in the interval, had an attack of pain in the *abdomen*, and shivering attended with fever, and died. An examination of the body not having been allowed, the precise cause of death was not ascertained." p. 844.

"The safest and best way," says **Copeland**, "is to pass a ligature round one only of the tumours at a time, the most painful and troublesome of them, and to wait until the patient has quite recovered from this operation before anything more be attempted, if anything more should be still necessary. * * * It is better that this operation by ligature should be repeated two or three times, if it should become necessary, than that the tumours should all be removed at once, at the imminent risk of the life of the patient." (pp. 64, 5.)

It is right that the day before the operation the patient's bowels should be cleared with castor oil or rhubarb, which prevents the necessity for disturbing them for a few days afterwards. **Brodie** recommends that the piles should be well protruded by sitting "over a pan of hot water, which will relax the *sphincter* muscle, and at the same time cause the veins of the *rectum* to become filled with blood. If this be not sufficient, let the patient have a pint or two of warm water thrown up as an enema, and when that comes away, the piles will probably descend. * * * Let the patient lean over a table, or lie on one side in bed, with his knees drawn up, the *nates* being held apart by an assistant. Each separate pile must be separately tied. If it be of a very small size, you may just take it up, with a double tenaculum, draw it out, and tie a ligature round its base. But if the piles be of large size, a large curved needle, armed with a strong double ligature, is to be introduced through the base of one of the piles, and the needle then cut off. The double ligature is now divided into two single ones, which are tied round the base of the pile; one on one side, and the other on the other, with a single knot. * * * When each pile is thus secured, cut off the convex portion of each pile, so as to make an opening into the cavity of the convoluted vein which forms it. Thus you take off the tension produced in the pile by the blood which it contains, and are enabled to draw the ligature tighter than before. It should be drawn as tight as possible; for then the subsequent pain will be less, and the separation of the slough quicker. A double knot having been made on each ligature, the threads are to be cut off close to the knots, and the piles, and the remains of the ligatures returned into the *rectum*. In about a week the ligatures are generally detached; and at this period the bowels should be kept gently open with lenitive electuary and sulphur, and cold water be thrown up the *rectum* every morning, in order to prevent a recurrence of the disease." (p. 844.)]

1549. The extirpation of the large swellings, degenerated piles, is performed in the following way. After the bowels have been emptied by a purge, and shortly before the operation by a clyster, the patient is to be placed on his belly with his buttocks raised, or upon his knees and elbows, or upon the side, in which case the opposite thigh is to be drawn up towards the belly, and the buttocks separated by an assistant. In internal piles, the swelling having been protruded by the pressure and straining of the patient, also after the employment of a warm hip or vapour bath, is to be grasped with broad-bladed forceps drawn forwards, and the *projecting part* cut off at one or more strokes with curved scissors. In the

---

(*a*) Œuvres Posthumes, vol. ii.

same manner external hæmorrhoids are to be treated. The most important thing to be dreaded, after the operation is bleeding; often is it inconsiderable, stops of itself, or can be stanched with cold water. When it is more severe, it may be most certainly stanched by cauterizing the bleeding part with a bean-shaped iron. The patient must always at first be attended by an experienced assistant, as after-bleeding, especially if it be not cauterized, is always to be dreaded (1). After the removal of an internal pile, there may be imminent danger without it being noticed. The patient always feels an increased warmth in the *rectum*, which is accompanied with the symptoms of concealed bleeding. A cold clyster must be immediately given; by straining and forcing, the blood must be discharged, and the bleeding part protruded, upon which the hot iron is to be applied. The inflammatory and spasmodic symptoms, as fever, colic, retention of urine, and so on, which soon come on after the operation, especially if cauterization be employed; must be got rid of according to circumstances by blood-letting, fomentations to the belly, introduction of the catheter, and anti-spasmodics. After the removal of large hæmorrhoidal swellings, a moderately thick bougie, smeared with cerate, must be introduced from time to time, to prevent a narrowing of the *rectum* (2).

Plugging the *rectum* may, indeed, be employed for stanching the bleeding; inconveniences are, however, connected with it, especially the continual pressure, extremely tiresome to the patient. The plug is also easily displaced, and its effect is not so certain as that of the hot iron (*a*).

[(1) When the bleeding after the removal of internal piles is profuse, and the patient will not submit to the actual cautery, Bush advises the use of an instrument which he "had constructed for suppressing hæmorrhage after lithotomy. This instrument is seven inches long, tubular, about as thick as a swan's quill, terminated with a button at one end, to facilitate its introduction, and with a stop-cock at the other. One inch from the stop-cock, and half an inch from the button, there are two projecting rings, and on the proximal side of the distal ring the tube is perforated by a number of holes. Finally, a portion of intestine is bound by means of waxed silk on the tube, behind the ring. This instrument should be introduced, and then inflated. In some little time we can let off the air and withdraw the instrument, provided the hæmorrhage has ceased; but if we find that it returns on the removal of the pressure, we must again inflate the intestine." (p. 185.)

(2) The elder Cline was accustomed to cut off piles; and Astley Cooper (*b*), for a time, followed the same practice, "thinking excision the best mode, because he found the pain produced by it very trifling as compared with the ligature." (p. 75.) But he met with several fatal cases from this method, which he very candidly mentions. In one case, "a very few days after removal of internal piles with the scissors, the patient complained of pain by the side of the *rectum;* an abscess formed under the *glutæus* muscle, which discharged abundantly; his constitution was already broken up, and he died in consequence of the discharge." In the second case he had removed internal piles, by excision, from a nobleman, without ill consequences, but, two years after, a similar operation having been performed on the same person, it was followed by frequent desire to go to stool, and four times he discharged a considerable quantity of blood. On examining, with a *speculum ani,* "one of the hæmorrhoidal arteries in the centre of one of the piles, which had been removed, was found divided." Cooper took it up; but the patient, being advanced in years and much weakened, was attacked with a severe rigor, grew gradually worse, and in four days died. The third case, operated on by another Surgeon, died from bleeding, on the fourth day. In the fourth case mentioned by Cooper, there was not any hæmorrhage; but, three days after, the woman was attacked with peritonæal inflammation, and died ten days subsequent to the operation. On *opening* the body, the *peritonæum* was found much inflamed, and had the appearance of death from puerperal fever. (p. 75-7.) Brodie employed excision for a time, but afterwards had three cases in which considerable quantities of blood were lost, and in the last, he observes, "so much, that he only wondered the patient did not actually die." Since then he has "never removed large internal piles except by ligature." (p. 843.)

THIRD DIVISION.

DISEASES DEPENDENT ON UNNATURAL COHERENCE.

First Section.—ON UNNATURAL COHERENCE IN GENERAL.

1550. The unnatural coherence of organic parts consists either in the union of neighbouring parts, which naturally are distinct; or in the formation of bad scars which diminish or destroy the movements of parts, by preventing their extensibility; or in a narrowing or closing of their outlets, by which their functions are considerably disturbed or rendered quite impossible. They are specially either consequences of previous inflammation, or vices of the original formation and congenital.

1551. In order that parts, which in their natural state are distinct, should unite together, a proper degree of inflammation, destruction of the skin, and long continued close contact are required. The union is either immediate, by means of a scarcely perceptible, interposed layer of plastic lymph, into which the vessels shoot; or it is fleshy, and depending on the development of granulations, and the formation of an intermediate substance, oftentimes having perfect resemblance to the parts it connects; or the connecting interposed matter is fibrous, membranous, in which case it would seem that there had been previously a more intimate connexion, which, in consequence of the movements of the connected organs, had formed these membranous lengthenings. For example, in the band-like adhesions between the *peritonæum* and the surface of the intestines, between the pulmonary and costal *pleura*. All organs are, under the above-mentioned conditions, capable of union; the serous structures and synovial membranes are most prone to it, the mucous membranes least so, and only when their surface is destroyed, and the underlying cellular tissue laid bare.

1552. When in a wound accompanied with loss of substance, especially in a severe burn, the treatment has not been conducted with due care, and the parts kept in proper position, the edges of the skin either greatly contract towards the centre, and a tough cord-like scar often connected with the underlying parts, or a superficial, prominent, knotty, misshapen scar is produced. In consequence of this the position and movements of the part are in various ways damaged or completely destroyed, or great deformity is produced. It must not however be forgotten, that in long continued unnatural position of a part, consequent on a scar formed in one of these ways, secondary contraction of the muscles, and alterations in the joints may be produced, by which the movements are still further restricted; and this condition may even become incurable.

1553. All the outlets are peculiarly constituted. They are either furnished with a true muscular apparatus, or at least are endowed with a special contractility, upon which their alternate expansion and contraction depend. Their inner surface is always overspread with mucous membrane, in consequence of which they can, exclusive of the cases from compression by neighbouring swellings and the like, be narrowed or closed in a variety of ways: thus, *first*, by spasmodic contraction, sometimes transient, sometimes continued; *second*, by hypertrophy, thickening and swelling of the parenchyma of the mucous tissue lining the outlet, consequent on previous inflammation, and on an unnatural vegetative process: *third*, by actual growing together, when for instance the mucous membrane of the outlet is destroyed; and, *fourth*, by scars which form at the edge of the outlet, or in its neighbourhood.

1554. The congenital closure of outlets, (*Atresia*, *Imperforatio*,) as well as the congenital union of parts, which should be separate from each other, (*Synechia*,) are arrested formations, in which the fœtus, at an early stage of its development, remains stationary, when the openings and clefts on the outer surface of the body do not yet exist, and parts which at a later period become separate, are still united together. The skin originally overspreads the whole surface of the body, and has on the parts where it closes the openings and clefts, the same character as elsewhere; it thins gradually, appears then as a peculiar secreting membrane, and is lastly removed by the process of absorption. As the *Atresiæ* are in the earlier stages of development of the fœtus, natural formations, so also are the *Synechiæ;* for instance, union of the eyelids with each other and with the eyeball; the union of the tongue, of the *glans penis* with the prepuce, and the like.

1555. If the closure of the outlets be a vicious primary formation, either the organization of the outlet is natural, and its opening only closed by a mere skin, though sometimes by a tough fleshy mass, or no trace of an outlet can be perceived externally. When the congenital closure of an outlet by which matters pass exists, it shows itself soon after birth, as in closure of the *anus*, *urethra*, and the like; but if it occur in those which only at a later period assume the peculiar condition of outlets, as, for example, the *vagina*, the closure is generally then first observable.

1556. The *treatment* of union of parts, which in the natural state are free and movable, requires division with the knife, together with the prevention of reunion, and all contact of the divided parts, by careful insertion of folds of linen, or lint besmeared with mild, and afterwards with drying ointments. The parts must also at the same time be kept in proper position, and during the period of granulation prevented by due application of caustic, from coming to that state in which they can again unite from the *angle* of the division; for which purpose, usually, pressure properly employed, is most efficient.

1557. In shapeless scars, which, by contracting parts, interfere with their position and movement, only in rare cases can any considerable relaxation be effected by the continued use of softening ointments, baths and the like; usually, by operation alone can improvement or perfect cure be effected; the management of which is different according to the condition and seat of the scar. If the scar be cord-like, tense, and by its shortness destroy motion, several transverse cuts may be made through its whole mass, and afterwards an apparatus put on, by which the parts shall be retained in natural posture, so that the formation of a *broad* scar may be effected. When the scar is broad, or united with the underlying parts, so however that its release is possible without injury to important parts, it must be cut out. The scar must be included between two cuts, and separated by careful dissection from the parts beneath, or the cellular membrane. If the skin in the neighbourhood of the wound be yielding, the edges of the wound, if it be not of very great extent, must be set free so far, that they may be united with the interrupted, or with the twisted suture. Although the edges of the wound be thus much stretched, and the skin also in the subsequent healing be still so, yet in a short time it yields, and all deformity disappears. When, as is commonly the case, this union is impossible, the wound must be treated as one suppurating, and retained by a proper apparatus in its straight posture. For the purpose of making the scar sufficiently broad, frequent touching with lunar caustic must be resorted to. I have, however, always found that, in consequence, correspondent condition of the scar is produced, that is, the tough, knotty projection can be prevented; but the special contraction of the edges of the skin towards the centre is encouraged. In all cases, therefore, in which I wish to form a broad scar, I only cover the suppurating parts with softening poultices or washes, and but rarely use caustic. When the scarring goes on tediously, there is always least disposition to contract, and the easier is it to produce a broad scar. If the scar project in knots and thereby be disfiguring, it must either be removed with the knife held flat, from its base, and the wound healed up in the usual way; or it must be cut completely out, and treated according to circumstances, after the above-mentioned rules.

On the different modes of treating deformed scars, compare

Beck; in Heidelb. klinisch. Annalen, vol. v. p. 213.

Dupuytren; in his Leçons Orales de Clinique Chirurg., vol. ii. p. 1.

1558. The narrowing and closure of the outlets require, according to their several causes, a different treatment. In spasmodic contraction, both local and general, corresponding antispasmodic remedies must be employed. If the narrowing result from an organic change of the mucous membrane, it must be specially ascertained whether, and what is the cause of the inflammation, which must be met with corresponding treatment. Should this, however, not be sufficient to get rid of the narrowing, the employment of mechanical means, which gradually widen the outlet, is required; or the removal of the hardened part of the mucous membrane must be attempted with the knife, with caustic, and the like. In these various modes of treatment, it must always be remembered, that should the natural calibre of the outlet be restored, the mucous membrane has always a peculiar disposition to reproduce the narrowing.

1559. The cure of imperforation is more or less difficult, in proportion as the seat of the closure is more or less deep, and depends on a membrane, or a fleshy mass. The closed part must be cut into, and its reunion prevented by the introduction of mechanical bodies. In closure of an outlet by membrane, if the latter be thrust down, in a flask-like form, by the collection of the excreted matters, the division is easy, and the skin must be divided with a crucial cut. But if the union be intimate and fleshy, the division is more difficult, and so much more so, in proportion to the greatness of its extent; it must always be made in the middle line of the union. If there be scarce any trace of the external opening of the outlet, the cut must be made in the direction in which it should open, and the outlet there sought for.

SECOND SECTION.—OF UNNATURAL COHERENCE IN PARTICULAR.

I.—OF THE UNION OF THE FINGERS AND OF THE TOES.

EARLE, HENRY, On Contractions after Burns or extensive Ulcerations; in Med.-Chir. Trans., vol. v.

—— Further Observations on Contractions succeeding to Ulceration of the Skin, in Med.-Chir. Trans., vol. vii.

BECK, K. J., Ueber die angeborne Verwachsung der Finger. Freiburg, 1819. 8vo.

SEERIG, Ueber die angeborne Verwachsung der Finger und Zehen, und Ueberzahl derselben. Breslau. 4to; with two lithographed plates.

1560. The union of the fingers with each other has different degrees of intensity and extent, and is either congenital or accidental, especially after burning the fingers. The congenital union arises, *first*, from bridges of skin; *second*, from connexions of skin and flesh; and, *third*, from running together of bone. The first kind of union is the most frequent. The natural formation of the finger may also be variously degenerated in these unions.

1561. The single mode of getting rid of these deformities consists, in dividing the union, which is alone contra-indicated, when the soft parts of the hand are grown together in an unshapely mass (1), and the bones of the fingers so run together, that there is scarcely any connexion by joints. Diseased condition of the skinny covering of the ill-formed hand, a highly scrofulous condition of the constitution, still existing inflammation, or great plastic activity, and the age of the party, may render the delay of an operation requisite. The time generally considered most suitable for operation, is the end of the first year of the child's life, and beyond that time, except for very special reasons, it should not be deferred. The fact, however, that even after the operation-wound has been perfectly healed, the fingers will again grow together, which depends partly on the deficiency of the skin, and its production not corresponding with the formation and growth of the finger, partly on the incompletely divided union stretching on with the enlargement of the finger, is of the greatest importance, and must, if the union of growth do not prevent, seem most properly to put off the operation, till the complete development of the finger (*a*.) The painfulness of the operation, as well as the ensuing inflammatory reaction, depend on the degree and extent of the union, on which account only one hand should be operated on at once, and the other at a more distant time.

(1) In a case in which the hands of a child presented only two lumps of flesh with a single undivided nail, five movable fingers were made, by cutting through the common cartilaginous mass (*b*).

1562. The result of the operation is often unsatisfactory, as reunion of the divided parts will occur, under the most careful treatment. This is to be especially feared at that period when the granulations rise from the hinder angle of the wound, and the edges of the wound draw together from both sides. To prevent this, various modes of operation have been proposed.

1563. In a simple, merely skinny union, after properly fixing the hand,

---

(*a*) SEERIG, above cited.

(*b*) LEROUX; Journal de Méd., vol. xiv. p. 275, p. 645.

a pointed bistoury is thrust, either with its edge towards the operator, somewhat above the angle of the natural junction of the fingers, vertically, through the connecting skin, and then divides it in the mesial line to the finger-tips; or the knife is carried from the points of the fingers backwards through the connexion. The irregularities of the edges of the wound are to be trimmed with the scissors. If the bones be also connected, the soft parts must be first divided with the bistoury, and afterwards the bony union, through the mesial line, with a little watch-spring saw. The dressings must be most carefully applied: a strip of linen, spread, at its ends only, with adhesive plaster, must be placed in the angle of the wound, and the two ends respectively fixed on the front and back of the hand. Over this a small long pad is placed, the surface of the wound covered with some folds of linen, spread with ointment, each several finger enveloped in a bandage, and the finger, by means of a piece of card-board or wood attached to the hand, kept as straight as possible; this may also be effected by particular contrivances (*a*). The dressing should be daily and very cautiously renewed once or under particular circumstances even twice, with strips of linen laid close in the angle of the wound; and towards the end of the cure, by a moderate application of caustic, the growth of the granulations there must be repressed.

Dupuytren (*b*) applied a narrow long pad with its middle on the angle of the wound, carried its ends to the fore-arm, and fastened them to an arm-bandage. He could not, however, by these means prevent the reunion. And he did not succeed any better with a narrow strap which he buckled to the arm-bandage.

1564. To prevent the reunion of the angle of the wound, which especially in firm union, is to be dreaded, Rudtorffer (*c*) thrusts a steel needle fourteen lines in length, the point of which is lancet-shaped, and its other end having a hole, for the reception of a leaden thread two inches long, vertically between the two united fingers, and thus introducing the leaden thread, bends and leaves it there. Cold water checks the bleeding and pain, and the sticking of the leaden thread is diminished by smearing the edges of the wound with oil. The thread is to be frequently moved, and the drying up and scarring hastened by use of lead wash. Beck (*d*) uses a lancet-needle ten lines broad with a leaden thread of equal width, which is left for some time, till the scarring of the edges of the wound. The leaden thread has a decided preference to the leaden plate, as by fixing its turned ends, pressure is always kept up against the angle of the wound, for with the leaden plate, with which this cannot be done, the growth at the angle of the wound goes on, and the lead is thrust out, as I saw in one instance.

1565. If the skin upon the back of the united fingers be sound and natural, it should be divided, according to Zeller (*e*), a little beyond the second phalanx; a V-shaped cut should then be made in the skin on the dorsal surface, with its point on the middle of the connecting substance. The skin should be detached, turned back, and, after the complete division of the union, this flap should be carried down between the fingers towards the palm, and fixed with sticking plaster. This treatment

(*b*) Leçons Orales, vol. ii. p. 36.

(*c*) Abhandlung über die einfachste und sicherste Operationsmethode ein gesperrter! Leisten- und Schenkelbrüche; nebst einem Anhange merkwürdiger, auf den operativen Theil der Wundarzneikunst sich beziehenden Beobachtungen, vol. ii. p. 478.!

(*d*) Above cited.

(*e*) Abhandlung über die ersten Erscheinungen venerischer Local-krankheitsformen, p. 109. Wien, 1810.

is rarely possible, as the skin is most commonly hard, callous, morbidly changed, and the flap commonly dies (*a*). **Krimer** (*b*) has, however, given some satisfactory reports of this operation.

1566. If the reunion of the fingers cannot be prevented, the operation must be repeated, but the inflammatory reaction and plastic activity must have completely subsided.

II.—OF GROWING TOGETHER OF THE JOINT ENDS OF BONES, OR ANCHYLOSIS (*c*).

Müller, Diss. de Anchylosi. Lugd. Batav., 1707.

Van Doeveren, Diss. de Anchylosi. Lugd. Batav., 1783.

Murray, Diss. de Anchylosi. Upsal, 1787.

Delpech, Précis Elémentaire, vol. i.

Barton, On the Treatment of Anchylosis, etc. Philadelphia, 1827.

Lacroix, De l'Anchylose; in Annales de l'Anatomie et de la Physiologie pathologiques, publ. par **Pigné**, 1843.

1567. Every intimate union of two bones, which naturally are connected together in a joint, produces complete loss of motion in the joint (*Anchylosis*, Lat.; *Gelenksteifigheit*, Germ.; *Ankylose*, Fr.)

Anchylosis is commonly divided into *true* and *false*. Under the former, is comprehended the loss of motion in a joint, depending on the union of the joint-surfaces; under the latter, that condition, in which the movements of the joint are only more or less interfered with, as is observed in long-continued inflammation of joints, in swellings of the ligaments, in tumours near the joints, in continued contraction of the muscles, and the like. This division is, to a certain extent, incorrect and objectionable, because, in the so-called false anchylosis, the hindrance of motion is only to be considered as a symptom of the disease, towards the removal of which the plan of treatment must be directed, and the union of the joint-ends of the bones is alone to be considered as the actual disease.

1568. The growing together of the joint-surfaces may be produced in various ways. It is usually consequent on inflammation of the parts composing the joint, especially when of some standing, and when the joint has been long at rest. If the inflammation go on to suppuration, and the cartilaginous surfaces be destroyed, if there be carious destruction of the bones, granulations may form, which, by shooting into each other, may become the means of union. Long-continued immobility of a joint may also cause an union of the surfaces. Although this is very rare, and may be readily distinguished, from the restrained motion which is consequent on habitual contraction of the muscles, on swelling of the ligaments and the like, observed after dislocation, and after the treatment of fractures, and may be got rid of by motion, softening rubbings, and so on, it is, however indisputable; although the ordinary explanation given of it, from want of *synovia*, or comparison of it with the obliteration of blood vessels, when the circulation is suppressed, is insufficient (*d*).

1569. According to the sort of union of the joint-surfaces produced, and its duration, is the nature of the connecting substance. It is either soft and yielding, frequently lengthening into ligament-like bands, or it is converted into an actual bony mass by the deposition of phosphate of lime.

(*a*) **Walther, Ph. F.**, Ueber die angebornen Fetthautgeschwülste, p. 32. Landschut, 1814. fol.

(*b*) **Graefe** und **Walther's** Journal, vol. xiii. p. 602.

(*c*) All the additions which seemed to me necessary, have been already made at p. 240, vol. i., in treating of Anchylosis as a termination of joint disease.—J. F. S.

(*d*) **Delpech**; above cited, p. 611.

1570. The *treatment* of anchylosis must be determined by the following circumstances. In most cases where anchylosis takes place, it is a desirable result, for example, in *caries* of joints, the so-called white swelling, and the like; and it should by no means be sought to prevent it, for all the attempts made with that object will only increase the inflammation, and the danger of the anchylosis. In such cases, therefore, the joint must be kept in the most perfect rest, and in such position, that the anchylosis ensuing will be most convenient and advantageous. Subsequently, when the inflammatory symptoms have disappeared, three conditions are possible: the substance connecting the joint-surfaces is either yielding, and by continued and gradually increased movements of the joint, may be lengthened into ligament-like bands, or these motions may reproduce the inflammatory symptoms, or they may be very difficult, and become every day more and more confined. In the first case, the movements are always accompanied with pain, which must be got rid of by emollient and soothing applications, rubbings in, bathing, and the like, and motion not carried to such extent as would produce fresh inflammation of the joint. In the second case, all motion must be avoided; and in the third, no effort can be in the least useful, because the mass has been already more or less converted into bone.

J. Rea Barton (*a*) sawed through the thigh-bone at the *trochanter*, in a case of anchylosis at the hip-joint, brought the limb into proper position, and by motion prevented union. He also employs this practice on other joints. It is only practicable when the patient is in good health, and when the stiffness depends on the soldering together of the bones, the soft parts at the same time being unaffected with disease, and all the muscles and tendons which contribute to the motions of the joint healthy; when the cause of the disease is entirely removed; when the operation can be performed so close to the original point of motion, or so near to it that the functions of the greater number of muscles and tendons can be preserved; and when the deformity and inconvenience is so great, that the patient is induced to subject himself to the pain and danger of such an operation. von Wattmann has obtained a favourable result by sawing through the upper-arm bone in anchylosis of the elbow joint. Dieffenbach (*b*) believes that the separation of the united joint by means of the chisel and saw, would not be more hurtful than the above-mentioned sawing through of the bone, to form an artificial joint, inasmuch as the anchylosed joint is no longer a joint, and therefore wounding it is not to be so much dreaded.

1571. The slighter degrees of the so-called false anchylosis, depending on contraction of the muscles or ligaments, or on contracting scars, may be completely removed by rubbing in suppling ointments, by relaxing baths, steam, and the like, with the simultaneous use of apparatus (1), which gradually straighten the joint. In the more severe forms of contraction little or nothing is effected in this way; in such cases, *violent and sudden extension; gradual extension with an apparatus, the tendons having been previously divided;* or, *sudden and violent extension soon after cutting through the tendons*, have been proposed and practised. The first mode of treatment (Louvrier's) is objectionable (2); the extension, by apparatus, after division of the tendons is generally tedious, must be very long continued, often produces considerable pain, and frequently meets with invincible obstacles; with it, however, no dangerous symptoms are to be feared. The violent extension after division of the tendons will considerably shorten the cure (Dieffenbach). This mode of treatment

---

(*a*) 'On the Treatment of Anchylosis by the Formation of Artificial Joints; in North American Med. and Surg. Journal, vol. iii. p. 279. 1827.

(*b*) Ueber die Durchschneidung der Sehnen und Muskeln, p. 249.

especially applies to the false anchylosis of the knee; it may, however, be employed in other joints.

(1) Of the various apparatus for extending the knee-joint (**Stromeyer**, **Duval**, **Bouvier**, and others) I think **Stretter**'s the most preferable.

(2) According to **Berard**, (*a*) of twenty-two cases of false anchylosis, treated by **Louvrier**'s method, three were fatal, on account of the severity of the violence; in neither was a well-formed joint produced; in the greater number there was dislocation of the knee backwards, and always renewed though slight contraction.

1572. In contractions of the knee-joint the patient is laid on his belly, that the crooked knee may project beyond the edge of the table. The tendons, having been rendered very tort by violently pulling the leg, are cut through beneath the skin, and the limb bent so strongly that the heel shall touch the buttock. It is then again forcibly extended, and again flexed, and this backward and forward motion is continued till the limb is straightened. Sometimes there is a loud crack, from the false connexions being thus torn through. In grown persons it often requires the united strength of three or four men, to break the knee-joint perfectly straight. Even in a case of true anchylosis, consequent on a penetrating wound of the joint, and its resulting suppuration, the breaking through of the united knee-joint, and the straightening of the limb, is required (**Dieffenbach**.) Immediately after the extension of the limb is effected, the knee-joint should be covered with pads, enveloped in a flannel roller, laid upon a padded hollow splint, and the splint and limb fastened together with a second flannel bandage. On reapplying the apparatus, the limb must be carefully cleansed, and in replacing it, much local pressure must be avoided, or slough of the skin will quickly ensue. After completion of the cure, the straight stiff joint must be carefully bathed and rubbed with suet. In many instances, if the joint again become flexible, the patient may be able to walk without halting (**Dieffenbach**.)

1573. Very severe symptoms may result from this violent extension of the limb, great inflammation, with its consequences may ensue, so as to render amputation necessary, and may even cause death. These emergencies, as well as the more or less favourable result of the operation rests, independent of the constitution of the patient, especially on the changes which have occurred in the joint itself and in the neighbouring parts. In contractions already long existing, and accompanied with great alteration of the joint, there is always a dislocation of the leg upon the thigh, from within outwards, or from without inwards; the shin-bone often gets under the thigh-bone, so that the foot is shortened, the knee-cap very prominent, and the ham less hollow; the condyle of the thigh-bone is often curved backwards, the whole limb wasted and atrophic. In such cases little violence is needed to dislocate the leg backwards. Even when by such alteration of the joint, the straight posture is effected, it has a most imperfect result, as the joint always remains more or less bent, the leg more or less placed behind the thigh, and the patient is only able to go on a crutch. In long-continued contraction of the knee-joint, the popliteal artery may be so considerably shortened, that extension of the limb cannot be effected without tearing it. (**Chassaignac**.) The splint-bone may be also so fast connected with one or other condyle of the thigh, or may be so thrust in between the shin- and thigh-bone, as to render the straightening of the limb impossible. If the contraction of the joint be only consequent on a

---

(*a*) Gazette Médicale de Paris, vol. ix. p. 324. Paris, 1841.

change of the surrounding parts, the result of the operation will be more favourable, as the joint will resume its natural form, power, and motion. In this case the joint is always more movable in the flexing direction. Great crookedness of the knee-joint often cannot be rendered straight after cutting the tendons; it will always crook again. The cause is, in this case, in the shortness of the lateral ligaments, usually in the external one, which is stretched under the skin, and must be cut through beneath it (*a*).

III.—OF THE GROWING TOGETHER AND NARROWING OF THE NOSTRILS.

1574. A complete closing up of the nostrils is more rare than their narrowing, and is commonly the result of ulceration and burns; it is rarely congenital. In slight narrowing, the malformation is inconsiderable, and usually requires no assistance. In more considerable narrowing, or growing together, the breathing is affected, especially at night, and the speech also. The connexion may be either at the edges of the nostrils, or the wings of the nose may adhere to its *septum*, and the growing together may extend more or less into its cavities. By the projection of the air in blowing through the nose, with the nostrils still open, the extent of the connexion may perhaps be ascertained.

1575. When the nostrils are merely narrowed, after an assistant has fixed the patient's head, a director is to be introduced into the nostril, and upon it a narrow straight bistoury, with which the narrowed part is to be cut through according to the form and direction of the nostril, which is thus widened. If the nostril be closed by a mere skin, this must be pierced with a bistoury, and its edges, having been taken hold of with forceps, raised and cut off. If the nostril be completely grown together, the bistoury must be thrust in the direction where the cavity should be, till it reach it, and being then withdrawn, and a director introduced, the bistoury is to be carried in upon it, and the connexion divided, as above described. This operation is always more doubtful, and its consequences less certain, the higher the connexion extends.

1576. After the division, the natural calibre of the nostril must be preserved by dressing, which is managed by introducing plugs of lint, or a quill wrapped with lint, by gum-elastic tubes, or Benjamin Bell's little tubes (*b*) smeared with lead ointment, and kept in position by a bandage round the head. The dressing must be renewed daily, all foreign matters removed, the nose cleaned, and after injection of lead wash, reapplied. If the introduced hard substances produce much irritation, plugs of lint must be used instead. This treatment must be continued till the opening of the nostril be completely skinned over, and even still longer, if we desire to avoid all disposition to a recurrence of the growing together or narrowing. When such disposition is noticed, it must be opposed by the use of expanders, sponge-tent, and the like.

On account of the great disposition to repeated closure, the operation must never be undertaken whilst the plasticity is still very active. When the narrowing of the nostril depends on unnatural formation of the bones, no expansion can be effected.

IV. OF UNNATURAL ADHERENCE OF THE TONGUE.

Petit; in Mémoires de l'Académie des Sciences. 1742.

Louis, Sur les Tumeurs Sublinguales; in Mém. de l'Acad. de Chir., vol. v. p. 410.

Oehme, De Morbis recens-natorum chirurgicis. Lipsiæ, 1773.

Lang, De Frenulo linguæ, ejusque incisione. Jenæ, 1785.

1577. An unnatural adherence of the tongue, by which sucking, the movements of the tongue, and proper articulation of the voice, are more or less prevented, may depend, *first*, on a tough, fleshy swelling of a brownish colour, and often nearly of the same size with the tongue, beneath which it lies; *second*, on the tongue-string (*frænulum*,) which either extends to the tip of the tongue, or is too short, (*tongue-tied* of common language, J. F. S.); *third*, on membranous connexions of the tongue on one or both sides; *fourth*, on union of the under surface of the tongue with the corresponding surface of the mouth.

The *diagnosis* of these conditions rests on examination. In children, by holding the nose, the mouth is made to open, and then with two fingers the tongue is raised and pressed towards the palate and sides. The examination is more necessary, as in many cases, the inability of children to suck from their mother and wet-nurse is ascribed to the tying of the tongue, whilst it really depends on other causes.

1578. When by this unnatural attachment of the tongue, sucking is prevented, or at a later period the speech is interfered with, the tongue must be set loose that it may enjoy free motion.

1579. In cases where the above-mentioned tumour is observed under the tongue, speedy assistance is always needed, which consists in cutting into the swelling. An assistant holds the child's nose, forcibly lifts up the tongue with the thumb and forefinger of the left hand, with its palm upwards, by which the fleshy mass is made more tense, and then it is cut into with a pair of blunt-pointed scissors. The wound generally heals in a few days, the spittle and milk render any topical application useless, and it is necessary to move the finger under the tongue frequently during the day, in order to prevent the reunion. In some cases it is advisable to scarify the tumour with a lancet, to diminish its size and give the tongue free motion. If the ranine artery or vein be wounded, it must be treated as already mentioned.

1580. The division of the tongue-string either when too short, or when reaching the tip of the organ, must be effected after properly raising the tongue, as in the former case, with the two fingers of the left hand, or with a spatula having a cleft in it for receiving the tongue-string, and rendering it tense, by **Schmitt**'s tongue-scissors, which, with their convexity upwards, are carried to the *frænulum* and cut through it, at a stroke, to the necessary extent. In doing this the scissors are directed as low as possible, towards the bottom of the mouth, to avoid injuring the ranine artery.

The instruments referred to are **Petit**'s spatula, with a snap-knife (*a*). **Benj. Bell**'s scissors (*b*). **Schmitt**'s scissors (*c*).

1581. When the tongue unites with the corresponding surface of the mouth, the child's mouth must be kept open by means of a piece of cork thrust between the jaws, and the tip of the tongue being raised with the

---

(*a*) Above cited, fig. 1, 5, 6, 7.

(*b*) Above cited, vol, iii. pl. xiii. f. 166.

(*c*) **Loder**'s Journal, vol. iv. part ii. pl. v. f. 1, 2.

fore and middle fingers of the left hand, the tongue must be set free with a curved bistoury to its proper extent.

[Occasionally, though not, I believe, very often, after severe sloughing of the membrane of the mouth, mostly after the use of mercury, the tongue contracts adhesion with the cheek. I have recently had one such case under my care, the only one I have seen, in which the side of the tongue was attached to the extent of half an inch. I applied a ligature around the band, which separated in three or four days, and set the tongue free. I preferred the ligature to snipping it through, lest there might be trouble from after-bleeding.—J. F. S.]

1582. The accidents which may occur after separating the tongue in the above cases are bleeding, and when the tongue has been divided to a great extent there is danger of suffocation. Attempts to stop bleeding of the wounded ranine artery must be made with little bundles of lint, moistened in styptics, THEDEN's arquebusade, or a solution of alum, which should be pressed against it with the finger; or the actual cautery may be applied to the bleeding part, which in all cases is preferable to the compressors of PETIT, JOURDAIN, and LAMPE. Bleeding may also be produced by the child sucking his tongue; in which case the blood will be swallowed. Care must, therefore, be taken for the first few days, that when he awake he be laid on his breast.

If there be danger of suffocation by the tongue turning backwards, it must be brought forward with the finger in the mouth, put in its place, and there kept by means of a thick pad put upon the tongue, and fastened by a bandage carried round the lower jaw; this must be removed as often as the child needs to drink (*a*).

1583. The membranous connexion of the tongue with the corresponding part of the gums, fixes the tongue either equally on both sides, or it is drawn to one or other side, according as it is unequally attached, or upon one side. The division of this connexion is always easily effected with the scissors.

V.—OF GROWING TOGETHER OF THE GUMS AND CHEEKS.

1584. The growing together of the gums with the cheeks is mostly consequent on inflammation and excoriation, the violent use of mercury, and the severe salivation following it, if the lips and cheeks be quiet. It may be of greater or less extent, by which chewing and speech are more or less hindered. It may be prevented in the above instances by frequently cleansing and injecting the mouth, by pencilling it with mucilaginous fluids, by the introduction of pieces of soft linen, by frequent movements of the parts, and introduction of the fingers; and, by the same means, an already formed agglutination may be got rid of. If the connexion be firmer it must be divided with a bistoury, and prevented reuniting.

VI.—OF NARROWING AND CLOSURE OF THE MOUTH.

DIEFFENBACH, Erfahrungen über die Wiederherstellung zerstörter Theile, u. s. w., sect. iii. p. 65.

ROST, G., Diss. de chilo- et stomatoplastice. Berol., 1836.

ZEIS, Handbuch der plastichen Chirurgie, p. 435.

1585. Complete closure of the mouth as a vice of the first formation, is very rare, and mostly accompanied with other vicious formations. A

(*a*) PETIT.

small opening must be first made in one or other corner of the mouth, whilst lifted up with the forceps; a director is then introduced, and upon it the closed membrane must be divided.

1586. Narrowing of the mouth frequently happens in consequence of large scars after the operation for cancer of the lip, or after any other wound with great loss of substance; usually, however, the mouth expands and the lips and cheeks retaining their extensibility, gradually allow its return to the ordinary form. But when there is a hard callous state of scar with simultaneous great loss of substance, and growing together of the membrane of the lips and cheeks with the gums, as after burns, destroying ulcers in *herpes rodens*, but especially after excessive and ill-employed use of mercury and the like, then such enlargement of the mouth will not follow, and three degrees of deformity may be distinguished; *first*, narrowing of the mouth from growing together of the internal surface of the cheeks and lips with the jaws, in which the external lips are unconcerned; *second*, the growing together of the mouth, and the conversion of the cleft of the mouth into a small round hole; *third*, destruction of the external lips with great loss of substance to a wide extent, so that the teeth are exposed, and the jaws cannot be separated from each other (DIEFFENBACH.) The inconvenience is various, according to the degree of narrowing; the introduction of food and chewing, is more or less difficult; the patient often can take only liquids with trouble; the nourishment fails, tartar collects on the teeth; the smell of the breath is very offensive, and the like.

1587. Widening of the mouth by cutting at both corners, as formerly advised, is useless, as the cut always again unites, and the deformity is worse. The treatment must vary according to the several degrees of narrowing and destruction of the lips.

1588. If the lips, otherwise unhurt, be connected by thread-like adhesions to the jaw, that part of the lip where the union is greatest, must be strongly drawn down, the tough scar divided, and the adhesions throughout their whole extent properly removed with the knife or scissors, as far as possible, to allow the lower jaw to be depressed. The mouth is then to be well washed with cold water, and frequently widely opened, and the cure usually soon follows. But if the entire surfaces be grown together, a corresponding portion of the sound membrane of the mouth must be separated to the thickness of common paste-board, applied over that part of the cheek opposite the meeting of the teeth, and fastened with the interrupted suture, so as to prevent the reunion of the wounded surface by the mucous membrane spread over it. When in these cases the breadth of the lips is narrowed by previous ulceration and proportionally shrivelled, no advantage will be derived by this operation, as they will always remain attached to the jaws. The enlargement of the aperture of the mouth must also be effected in the way above mentioned.

1589. In considerable narrowing of the mouth from its growing together and firm scarring, which mostly affects one or other corner of the mouth, or even both, DIEFFENBACH's (*a*) and WERNECK's (*b*) modes

---

(*a*) RUST's Magazin, vol xxv. p. 383, and work above cited, p. 44.

(*b*) Ueber die künstliche Mundwinkel- und Lippenbildung durch blutige Umschlagung der Mundhaut; in VON GRAEFE und WALTHER's Journal, vol. iv. p. 202. His mode of treatment is similar to DIEFFENBACH's, but published subsequently.

of treatment are the best. A thick strip of the entire soft parts, down to the mucous membrane, which must be left uninjured, is to be cut from the mouth at one or both sides; for which purpose, the pointed blade of a pair of sharp scissors thrust into the corner of the mouth is carried to some extent between the soft parts of the cheek and the mucous membrane, and the cheek cut through to the part where the angle of the mouth is to be formed. From the lower corner of the mouth, a cut parallel to the former is connected by a short circular cut. The piece of skin thus circumscribed, is now to be completely separated from the mucous membrane, and afterwards the other side similarly treated. When the bleeding is stanched, the lower jaw must be much depressed, by which the exposed mucous membrane will be considerably stretched, and must then be separated for a few lines from the membrane of the cheek, and divided in the middle, but not so far as the corner of the mouth. After stanching the blood and closing the wound, the mucous membrane must be drawn out over its edges, and the edges of the membrane connected around with fine needles and the twisted suture. The mucous membrane folds opposite the middle of the lip which has not been disturbed. The part of the mucous membrane not cut through should be well drawn out at the corners.

The bloodless expansion of the mouth with sponge-tent, and the like, is useless. Horizontal cuts on either side, as formerly recommended for widening the mouth, are unavailing, inasmuch as they always re-unite, and the person's condition is worse. The practice of Krüger-Hansen (*a*), who, after Rudtorffer's statement in reference to united fingers, (*par.* 1555,) made an opening with a trocar into a mouth half closed by a callous scar, at the point where its boundary was to be fixed, in which he allowed a leaden thread to remain till the part had skinned over, after which the remaining cut was made, is tedious, uncertain, and produces a callous aperture for the mouth.

1590. If with narrowing of the mouth there be such loss of substance in the lips, that the teeth are exposed, and the jaws cannot be separated from each other, and in which often the small opening of the mouth is dragged upon the cheek, the deformity can be only somewhat improved, and the patient's condition alleviated, after careful examination of the peculiarity of the case, by cutting out the hard scar, loosening the attachment to the jaws, drawing over the skin, and the like.

Compare also an interesting case of a similar operation of Dieffenbach's (*b*).

(*a*) von Graefe und Walther's Journal, vol. iv. p. 543.

(*b*) Erfahrungen, sect. iii. p. 110.

1591. Narrowing of the *œsophagus* may be produced by various causes; by scars after wounds or burns (*par.* 474); by the swelling up of its walls consequent on chronic inflammation of its internal coat; by scirrhous or callous hardening; by fungous, polypous, or warty growths; by a varicose condition of the vessels; by tumours, especially swellings of the glands which compress the *œsophagus;* and by spasm.

Hoederer (*a*) observed an *œsophagus* with a blind end in a monster. The same was also seen in a full-grown and otherwise well-formed child (*b*).

1592. The consequence of narrowing of the *œsophagus* is more or less interfence with swallowing; the symptoms, however, vary according to the kind and seat of the narrowing.

1593. In *simple* (*membranous*) *stricture,* which, resembling a fold of the internal membrane of the *œsophagus,* occupies only a small extent, and is usually situated at the upper part of the tube, opposite the cricoid cartilage, the patient first feels, at one particular spot, a slight difficulty in swallowing solid food, and, when the food passes over the part, often a shivering in the back. This difficulty continues a longer or shorter time, diminishes or ceases, and reappears without any particular cause, or after a chilliness, mental emotion, and the like. The disease may thus long continue getting better and worse. Earlier or later, the difficulty in swallowing becomes greater, large pieces of food will be retained at that particular part of the *œsophagus,* in consequence of which, symptoms of choking, with the sensation of a violent, spasmodic contraction of the neck, cough, and great straining are produced, by which the food, frequently with an audible grating noise, passes over the obstacle, or by the contraction of the walls of the *œsophagus,* and the straining of the patient, is returned to the mouth, and thrown out. The difficulty in swallowing is now constant, and increases more slowly or quickly, so that the patient can swallow less and less food, with the above-mentioned symptoms; at last can swallow it no longer, and is reduced to the use of thin broths and fluids, in the swallowing of which even, the same symptoms come on. Even when the difficulty in swallowing is constant, there is often, from time to time, a little improvement, for which, however, as well as for the subsequent aggravation, no reason can be assigned, if accompanying spasmodic affection be not assumed. With the increased difficulty of swallowing, the patient's nourishment is affected; he wastes to the most extreme degree, and is starved to death. In this form of stricture of the *œsophagus,* there is, however, no further appearance of any specific morbid reaction.

1594. The change by which the internal membrane of the *œsophagus* causes this narrowing, in which it forms a fold-like projection, capable of contracting itself to the smallest aperture, generally depends on an inflammatory condition of the mucous membrane of the *œsophagus;* frequently, however, no decided cause can be found; oftentimes it occurs after a cold. At the beginning, the disease, on account of its getting alternately better and worse, is thought to be a spasmodic affection; it is, however, probable that a spasmodic affection may pass into permanent stricture. This form of narrowing of the *œsophagus* occurs more frequently in mid-life, and, according to my experience, more frequently in women than in men; I have, however, noticed it in persons of fifty or sixty years of age.

Home (*c*) has given a beautiful engraving of a membranous stricture.

(*a*) Commentar. Societ. Goetting., vol. iv.

(*b*) **Harless**, Rheinisch. Jahrbüchern der Med. und Chir., vol. i. pt. 2.

(*c*) Above cited, p. 422.

1595. The *callous narrowing* of the *œsophagus* mostly consists of a circular thickening of the walls of the tube, at a particular spot; it may, however, be variously spread, often only one or other wall of the *œsophagus* is affected to a different extent. It is generally, from the first, accompanied with great inconvenience; the food, at the moment of swallowing, causes violent pain, mostly between the shoulder-blades; it is thrown up, and commonly also with it a morbidly large quantity of tough mucus, secreted from the almost entirely closed breathing passages. The patient assists himself by throwing himself back, stretching out his neck, and similar movements, in order to carry the food over the seat of narrowing; oftentimes the food passes on with a noise and cessation of pain; afterwards every portion of food is returned, with a gurgling noise and violent cough. This disease also for a time yields, and usually makes slow progress; I have, however, seen in one case the patient starved to death in three months, and on examination a circular, regularly callous thickening of the walls of the *œsophagus* was found at its upper part, and gradually lost itself both above and below.

1596. In *scirrhous hardening* of the walls of the *œsophagus*, which otherwise in its symptoms has great resemblance to the callous condition, and is generally situated at the lower part of the *œsophagus*, and even at the *cardia*, the difficulty in swallowing usually increases slowly, and the patient has also a dull, weighty, dragging, and often very painful sensation at the part, especially opposite the spine, which diminishes on lying down.

1597. The symptoms and accidents in this stricture of the *œsophagus*, are especially different in reference to its seat and extent, and particularly as regards the condition of the *œsophagus* above the stricture; as when, as is frequently the case, it is considerably expanded, the food that is swallowed, collects in great quantity, and is only afterwards thrown up.

The expansion of the walls of the *œsophagus* is either of the whole of the canal, or only partial, and depends on the protrusion of the internal coat between the separated fibres of the muscular coat, so that a sac of various size is formed (*Diverticulum, Hernia Œsophagi, Œsophagus succenturiatus,* &c.) This partial expansion occurs also frequently without any narrowing of the *œsophagus;* at least, I have never observed it with, but twice without stricture. It depends on the excessive expansion or tearing of some muscular fibres in the swallowing, and sticking of large, hard pieces of food, and the like. The food gets into this sac, expands it still more, and sooner or later, without any straining, is thrown up into the mouth. Whilst eating, the patient, when this sac is full and at the upper part of the *œsophagus*, must, as I have witnessed, empty it, from time to time, by pressure with the fingers, so that he may be able to swallow better.

1598. In the *scirrhous and callous, cartilaginous and bony, narrowing* of the *œsophagus*, which occurs, specially after the abuse of spirituous liquors, from the habit of eating and drinking very hot things, from the suppression of the ordinary discharges, from the venereal disease and alike, generally in advanced age, and in men, ulceration comes on at the later period, by which part of the stricture is destroyed, and symptoms of hectic consumption ensue. When these strictures are of long continuance, the ulceration always begins on the side next the stomach, which must be attributed indeed to the frequent efforts to vomit, by which the walls of the *œsophagus* below the stricture are deprived of their natural activity and natural moisture. The ulceration is usually seated on the hind wall of the *œsophagus* next the spine, and not unfrequently attacks the bones; it may, however, destroy the front wall and the corresponding part of the *trachea* or *bronchi*, and a communication may be produced between them, in which case most violent cough, choking on every attempt to swallow, and hæmorrhage are produced.

I have seen one case of callous stricture in a man sixty-three years old, in which there was a communication between the right *bronchus* and the *œsophagus*. MEYER (*a*) relates an instance of strictured *œsophagus* with a communication between the left *bronchus* and the *œsophagus*. GENDRIN (*b*) communicates two cases of narrowing of the *œsophagus* at the region of the cricoid cartilage, in which there was also a fistulous orifice into the *trachea*, and cough in swallowing, vomiting fluids, speaking through the nose in consequence of the changed direction given to the air.

1599. In *narrowing of the œsophagus from fungous growths*, fluids usually pass with more difficulty than solids; if the food be again thrown up, it is usually mixed with bloody mucus, and membranous fibres, which even on examination with the sound, present a yielding obstacle and become attached to it.

1600. The *compression of the œsophagus by swellings* of any kind in its neighbourhood, can be ascertained by careful examination of the neck; the difficulty of swallowing corsesponds with the growth of these tumours, an *œsophagus* sound will pass more readily in this disease than in stricture. If such swellings be seated in the chest, the *diagnosis* is also more doubtful.

See also in KUNZE (*c*) the different observations on these swellings.

Here also belongs the so-called *Dysphagia lusoria* depending on the unnatural course of the subclavian artery by which the *œsophagus* is compressed. BAYFORD (*d*) first described it under this name, and his observations have been confirmed by others. (RICHTER (*e*), VALENTIN (*f*), AUTENRIETH) (*g*). By some this cause of *Dysphagia* is denied, (FLEISCHMANN (*h*), RUDOLPHI,) because the unnatural course of the subclavian artery has been noticed without this disease; and this notion is settled by SCHÖNLEIN, as the origin of the dysphagy in this unnatural course of the subclavian artery depends on whether the artery pass before the *trachea*, between it and the *œsophagus*, or between it and the spinal column, in which latter case the disease must take place. The inconvenience first appears at the period of puberty, or on the suppression of menstruation, when the congestion towards the chest is greater. The symptoms are, violent palpitation and danger of suffocation on every attempt to swallow, accompanied with tremulous intermitting, and specially weak pulse in the right hand: the right arm is also shrunk and weaker; twisting movements of the neck frequently cause pain; all the inconvenience is in swallowing alone, and even then often only periodical.

1601. The *spasmodic stricture of the œsophagus* is usually seated more at the lower part towards the stomach, and is accompanied with the sensation of the tying together a fast-fixed substance; sometimes the organs of swallowing and the muscles of the neck are in spasmodic tension; the evil is increased by cold drinks, and diminished by hot ones. It is accompanied with spasmodic symptoms in other organs, qualmishness, vomitings, cough, secretion of a watery mucus, not unfrequently symptoms of suffocation, loss of speech, and the like. The spasm frequently intermits; this affection may, however, continue for a long while, which renders the *diagnosis* difficult; and also that, probably, during this long continuance, membranous stricture (*par.* 1594) will be produced. If spasm be added to organic stricture, the symptoms will be quickly increased.

(*g*) Pfleiderer (Præs. AUTENRIETH) Dissert. de Dysphagiâ lusoriâ. Tubing., 1806.

(*h*) Neue Schriften der Erlanger phys. med. Gesellsch., vol. ii.

There is a difficulty in swallowing, which may amount to the greatest degree of dysphagy, dependent on a *chronic inflammatory*, and consequent spasmodic affection of the upper part of the *pharynx*, and which, on account of its usual connexion with impetiginous diseases, and the peculiar change of the mucous membrane of the *pharynx*, I have distinguished as *Angina impetiginosa.* This disease develops itself without any decided cause, and after a catarrhal affection of the throat. The difficulty in swallowing increases gradually to a very great degree, so that it is often quite impossible for the patient to swallow, and the smallest portion of food or drink is thrown up, with which there are also spasmodic contractions in the throat, and difficulty of breathing. It is a peculiarity in this complaint, that it is more difficult to get down fluids, than more consistent mucilaginous substances; there is often such dread of fluids, that when brought to the mouth there is the most violent spasm of the *glottis*, so that every attempt to swallow is impossible. If the throat be examined by proper compression of the tongue, the hind wall of the *pharynx* is found to be especially changed; the mucous membrane has a net-like or latticed appearance, and between the paler streaks are perceived a few light red island-shaped elevations. The redness is very indistinct, rather pale, and inclining to yellow; at several parts there is a sort of papular and phlyctenous formation. The patient complains usually, besides the difficulty in swallowing, of a burning or stabbing pain at some one part of the throat; he has often the sensation as if several little knots or bladders had formed and burst, after which a wound, very sensitive to the touch, remains for some time. These sensations, as well as their places, alternate irregularly. The patient has frequently the sensation of a circular contraction at the upper part of the *œsophagus.* I have noticed this disease in young and old persons, and always perceived a certain disposition to previous, though inconsiderable chronic affection of the skin. The resemblance of the symptoms may mislead to the presumption of an organic stricture, and many patients in this condition have been sent to me by distinguished practitioners; but an examination, with the œsophageal sound is, on account of the excessive sensibility of the throat, impossible, and the alternation of the symptoms, and especially the peculiar appearance of the back of the *pharynx*, can alone determine the *diagnosis.* The *treatment* is one of the most difficult questions. In a young man the disease had withstood, for many years, the most different and severe remedies, both internal and external, employed by several practitioners; at last he submitted to mine; but, up to the present time, the observations I have made point out no definite rule. Close consideration of all the previous circumstances, and constitutional relations, must lead the practitioner in the treatment, which requires equal perseverance on the part of both him and the patient. In one instance, repeatedly touching the back of the *pharynx* with lunar caustic seemed effective. To a certain extent this condition may be compared with the spasmodic contractions of the *sphincter*, in *fissura ani.*

1602. The *prognosis*, in stricture of the *œsophagus*, depends on the kind and seat of that affection. The simple, membranous stricture admits a favourable *prognosis*, and may be completely got rid of by proper treatment. Callous and scirrhous stricture rarely allows any check to its development, and, when once existing, its alleviation is scarcely possible, and still less its cure. Spasmodic stricture may mostly be got rid of by proper treatment; the disease however often recurs, is frequently very stubborn, and may run into organic stricture. In swellings which compress the *œsophagus*, the *prognosis* depends on their nature and seat.

[Astley Cooper (*a*) mentions a case in which, during stricture of the *œsophagus*, an aperture was made from it outwards by ulceration; the patient was kept alive some time by administering food through an elastic catheter.—J. F. S.]

1603. In those cases in which the alteration of the mucous membrane of the *œsophagus* depends on chronic inflammation, a strict attention to the mode of living accompanied at first with antiphlogistic treatment, repeated leeching, the continued internal use of hydrochlorate of ammonia, of hemlock, of mercury, of iodide of potash, with simultaneous derivation by issues, tartar emetic ointment, setons, and the like, together with carefully-regulated living, are required. The progress of the stricture is, however, rarely checked by these means; and its existence may be

---

(*a*) MS. Lectures.

ascertained, in addition to the symptoms described, by the introduction of a sound, in the way presently to be described, which finds a distinct obstruction, and is stopped at the seat of stricture.

1604. The introduction of an œsophageal sound is the most simple remedy to get rid of an existent narrowing, by gradual extension. This treatment in membranous stricture ensures a satisfactory result; in callous and scirrhous stricture it is never, according to my experience, to be relied on. The introduction of the sound has frequently only the palliative effect of prolonging the patient's life, by the passage of food into the stomach. In such cases, however, the irritation of the sound may, without delay, drive on the stricture into malignant degeneration and ulceration.

1605. The introduction of a sound into the *œsophagus* must be conducted with the greatest care and delicacy, or otherwise injury to the walls of the *œsophagus*, false passages, and hastening the miserable end of the disease will be produced. The following is the best mode of proceeding. The patient sits upon a chair, his head moderately thrown back, and held by an assistant, his mouth wide open, and tongue a little protruded (1). The œsophageal sound provided with a leaden stilette, oiled, and a little curved at its tip, is then introduced into the gullet, and gently pushed onwards. When it has reached the seat of stricture, care must be taken, and an attempt made, by gentle pressure, to overcome the obstacle, over which it usually slips with a jerk and can then be passed still farther. If it be impossible to get through the stricture with the sound, a thinner one must be chosen and used in the same way. In some cases of great narrowing, I could only succeed, after several fruitless attempts with the thinnest œsophageal sound, in passing through the stricture with a moderate-sized urethral sound. The instrument thus introduced, and the stilette withdrawn, must be allowed to remain as long as the patient can, without much inconvenience, bear it, which at first will not exeeed five minutes. In general, the swallowing after this first introduction of the sound, very small though it be, will be remarkably improved. The sound should be passed daily in this manner, and allowed to remain a little longer, so that the parts may become accustomed to the irritation, and then by degrees a thicker sound may be used.

The introduction of the sound through the nostril is improper, much more painful to the patient, and, if it be thick, impossible; by this mode also the instrument more frequently slips into the windpipe, than in passing it by the mouth. This is proved by the violent disposition to cough, by the expulsion of the air with the sound, and the impossibility of speaking; it is right, however, to observe that frequently the disposition to cough, although the sound be thrust into the windpipe, is not so great; and that by the choking, when the sound is in the *œsophagus*, the air may be forced up from the stomach with a hissing noise.

The introduction of the sound, provided with a leaden stilette, if the instrument require passing to a great depth, has the advantage of giving to it every desirable and suitable curve. The sound can be introduced with the greatest safety, without interfering with the curve of the leaden stilette and is rendered more steady than without it. In very narrow strictures, in which the thinnest sound will not penetrate, it is better to employ the thinner urethral sounds than that the obstacle should be overcome with violence, as BOYER (*a*) did in one case, in which he employed a silver catheter, passing it through the mouth, and, having passed the obstacle, then introduced an elastic sound, the end of which he carried by the assistance of BELLOCQ's tube into the nostril. Any great force used in introducing an œsophageal sound endangers tearing the walls of the *œsophagus*. I knew one instance abroad, in which the sound penetrated the hind wall of the *œsophagus* above the stricture, proceeded some distance between it and the spine, and below again entered the *œsophagus*, as proved by dissection. In difficult cases,

---

(*a*) RICHERAND, Nosographie Chirurgicale, vol. iii. p. 262. Third Edition.

a sound, made of modeller's wax, may be employed, with which slight pressure may be made against the stricture, and an impression of it obtained as I have sometimes observed (2).

[(1) The practice here recommended, of protruding the tongue, preparatory to passing the sound or bougie, and which, I believe, was first recommended by **Home**, is very objectionable, as in proportion must the *epiglottis* be raised, and greater facility for the entrance of the instrument into the windpipe afforded. Moreover, it is quite needless, as the passage into the beginning of the *œsophagus* is rendered easy by placing two fingers of the left hand upon the tongue, and pressing it into the bottom of the mouth, which readily exposes the whole cavity of the *pharynx*.

(2) **Astley Cooper** (*a*) used to mention a case of this kind; he had been called to a person with stricture of the *œsophagus*, and had attempted to introduce an urethral bougie, but in vain. Another Surgeon was called, who passed an instrument, with readiness, as he said, and then injected some milk and wine through it. A swelling immediately arose at the upper end of the breastbone, and the patient cried out, "Oh! you burn me." The same evening the man was dead. The instrument had been thrust through the *œsophagus* into the anterior *mediastinum*, into which the fluids had been poured. The preparation of the parts is in the Museum at St. Thomas's Hospital. —J. F. S.]

1606. If in this way much expansion of the stricture can be effected, and swallowing be in a corresponding degree improved, for the purpose of sustaining a continual cure, a sound with an olive-shaped dilator must be used, which after some days must be changed for a thicker, and, according to circumstances, for the thickest. In introducing a sound with a dilator, as in passing a common sound, care must be taken that the dilator be pushed gently through the seat of stricture, which is distinctly marked by the resistance. The instrument is either moved up and down a few times through the stricture, or, when it is ascertained that its thick part is in the stricture, it may be left there for some time, and then drawn back. I have never observed that in thus doing the patient has suffered much inconvenience. The sound with the dilator is generally borne as well as the common œsophageal sound. When the swallowing has become perfect, the sound should not be given up, but passed once a week or fortnight, to counteract the disposition to narrowing again, which I have also endeavoured to prevent by introducing a seton in the neck for some time.

This treatment has, in all cases of membranous stricture in which I have employed it, effected a permanent cure. The dilator is either made of ivory, slipped on the sound at some distance from its tip, and there fastened, or the sound itself is furnished with a bellying enlargement of caoutchouc at the same place. These dilators are of various thickness, up to an inch in diameter. The mere introduction of a common sound, up to the largest size, may relieve and improve the patient's condition for some time, and may produce even complete freedom of swallowing; but a permanent result is not thereby commonly produced; earlier or later the disease recurs.

The use of bougies, armed with lunar caustic, for the destruction of stricture of the *œsophagus* (*b*) must be considered highly dangerous in every form of the disease. **Jameson** (*c*), instead of the gradual violent extension of the stricture, employs an oval ivory dilator, which he uses either alone or with a sound, or with a sound armed with a bullet, passed three or four times through the stricture.

Fletcher (*d*) uses a metallic instrument, which either serves for tearing, or merely dilating the strictured *œsophagus*. It is curved in front, consists of three close-lying branches, and, when the instrument is introduced into the stricture, they are separated by twisting the handle. The use of this instrument is, in my opinion, accompanied with great difficulty, and, in stricture deeply situated, it is not at all efficient. The introduction of a whalebone stem, commonly known as a probang, with a sponge (*e*) for the purpose of expanding the stricture, is not proper.

1607. In membranous stricture, besides the above-described, no further treatment is necessary. In callous and scirrhous stricture, the previous mentioned (*par.* 1603) treatment, both internal and external, must be simultaneously employed. Spasmodic stricture requires the use of anti-spasmodic remedies, especially ipecacuanha in small doses, and the application of ***emp. belladon.*** around the neck. The introduction of the sound has often, in these cases, better effect than any other treatment.

In *Dysphagia lusoria,* the congestion about the chest must be relieved by strict attention to the mode of living, the blood must be diverted to the lower parts, suppressed menstruation restored, and the like. Autenrieth recommends also the frequent introduction of the œsophageal sound, for the purpose of relaxing the *œsophagus,* and to lengthen and strengthen the cellular tissue connecting that tube to the arteries.

1608. If the sound be used for the purpose of introducing strong broths, one should be employed which has a funnel-shaped horn mouthpiece. The sensation of warmth which the patient feels in the epigastric region is a proof that the fluid has entered the stomach. Previous to administering the fluid, attention should be paid to the symptoms described (*par.* 1605) as occurring on accidental introduction of the sound into the windpipe.

The *Dysphagia paralytica atonica,* which occurs in old persons after apoplexy and nervous diseases, in which the patient cannot mention any decided obstacle, any pain, or tightness does not offer any opposition to the sound, and the breathing is not interfered with ; tough mucus is often spat up ; solid food and bits of bread usually pass better than fluids, sometimes better when swallowed slowly and in the upright posture; and frequently there is a greater or less degree of accompanying palsy of the tongue. The introduction of the elastic sound is required when the patient cannot be sufficiently nourished. I have found gargles of *tinct. rad. pyrethri* especially useful, also blisters to the neck, and arnica.

von **Ammon**, Chirurgische Pathologie in Abbildungen, part i. pl. x..

1609. *Closure of the Rectum* (*Imperforatio, Atresia Ani*, Lat.; *Verschliessung des Mastdarmes*, Germ.; *Imperforation du Rectum*, Fr.) is always a vice of the first formation; but *Stricture* (*Strictura Ani*, Lat.) *Verengerung des Mastdarmes*, Germ.; *Rétrécissement du Rectum*, Fr.) most usually arises subsequently, and is rarely congenital.

1610. The congenital closure of the *rectum* depends either on a simple membrane, which more or less resembles the general coverings or the intestinal membrane of the gut, and is situated either immediately at the anal aperture, or more or less high in its cavity; or there is not a trace of *anus*, and the *rectum* opens more or less high in a blind sac. Those cases of congenital malformation must be now also mentioned, in which the *rectum* opens into the urinary bladder, *urethra*, or some other aperture, whilst the *anus* is closed.

Compare von **Ammon** (*a*) upon the unnatural openings of the *anus*, and the other malformations therewith connected.

1611. Closure of the *rectum* always causes violent forcing and straining; with which, nothing being discharged by the *anus*, painful tension of the belly, vomiting of green or yellowish matter, arise; and to these symptoms convulsions are afterwards added. If the *rectum* be closed by a simple membrane, it is, especially when the child cries, protruded like a sac, and the *meconium* is seen through it. If the closing membrane be higher, it is ascertained by the introduction of the finger or of an elastic sound.

[Although imperforation of the *anus* or *rectum* is generally soon discovered by the child not passing motions, yet a case is mentioned by **Wolff** (*b*), in which it was not found out till the evening of the twelfth day after birth, when the child was attacked with vomiting, hiccough, and convulsions; the belly was very full and tender. The *anus* was found imperforate, but the gut could not be opened by a lancet thrust in to the depth of two inches. A pharyngotome was then passed up, and with it an aperture made, and by the use of clysters and tents the child ultimately recovered.]

1612. If the external opening of the *rectum* be closed by skin, it is sufficient to thrust into it a straight bistoury, and to enlarge the wound with a button-ended bistoury on a director; and, if it seem necessary, the flaps thus formed may be removed with the scissors. If the closed part of the *rectum* be higher up, a narrow, straight bistoury must be introduced, in a proper direction, upon the forefinger of the left hand, or upon a director, through the closing membrane, and the opening thus made enlarged with the button-ended bistoury; a trochar or a pharyngotome will answer the same purpose. This treatment is, according to the kind of closure, accompanied with more or less difficulty; the expanded part of the *rectum*, instead of the seat of closure, may be lighted on, and fatal effusion into the *pelvis* follow. The closed part may be hard, callous, car-

(*a*) Cited at head of article.

(*b*) **Langenbeck's** Bibliothek, vol. iii. p. 231.

tilaginous, and very thick. To prevent the re-closure of the *rectum*, it is necessary to insert a plug of lint, fastened up with strips of sticking-plaster, and with a thread attached to it, for a long while in the cavity of the gut, or to introduce the finger, well oiled, from time to time into the *rectum*, as the disposition to re-close is often very considerable (*a*).

1613. When there is no trace of an external anal opening, the difficulty of the operation depends on the higher or lower position of the blind end of the *rectum*. If there be no fluctuating swelling, no accompanying projection or depression, which can direct the practitioner, he then, after carefully introducing a catheter into the bladder, and in a female a sound into the *vagina*, for the purpose of emptying the urine, and distinguishing, during the operation, the position of the bladder and *vagina*, makes a cut with a pointed bistoury between the beginning of the *raphe* and the *coccyx*, in such way, however, that there be an inch distance between the latter and the cut, as in children the *rectum* does not lie so close to the *coccyx* as in adults. Having penetrated about half an inch, the finger of the left hand must be introduced into the wound, the blind end of the gut sought for, and then the cut is to be cautiously continued more deeply, following, as far as possible, the course of the straight gut, and taking care not to wound the bladder or *vagina*. When the cavity of the *rectum* is penetrated, the aperture made must be enlarged with the button-ended bistoury, on the finger or on the director, and the dressing to prevent the re-closure applied in the usual way. If the penetration have reached a depth of two inches, without coming to the gut, it has been advised to proceed with the operation by thrusting a trochar towards the blind end of the *rectum*; the objection, however, seems to be correct, that the operation is equally hazardous and useless, as, although the gut may be opened, effusion of *meconium* into the belly is the consequence (*b*). Here also may be mentioned AMUSSAT's (1) mode of practice, in which he draws forth the blind sac of the intestine exposed by the cut, opens it, and attaches the cut edges of the gut to the edges of the external skin.

(1) AMUSSAT (*c*) found, on introducing his finger into the *vagina*, a movable body on the top of the sacro-vertebral articulation, which he took for the end of the *rectum*. He made one transverse cut behind the proper seat of the *anus*, and then another which reached the *coccyx*. Through this T cut he introduced his finger, carrying it along the *sacrum* to the end of the gut, and therewith broke down the adhesions; he then drew the intestine, with a pair of forceps, to the external opening, cut into it, and fixed it with two stitches, so that the mucous membrane overlapped the edge of the external skin.

[Sometimes the two portions of the ileo-colic valve are adherent to each other, so as prevent the passage of the *meconium*, and lead to the presumption of the large intestine being imperforate in some part of its course. A case of this kind occurred to me at the General Lying-in Hospital, in the summer of 1842. The child was born at 1 A.M., June 6; and some hours after, no motion having passed, castor oil was given, but did not operate. On the evening of the same day, an elastic catheter was introduced into the *rectum*, to the extent of two or three inches, and no obstruction being met with, the castor oil was repeated, but did not produce any stools. On the following morning an attempt was twice made to throw up an injection, but it failed; and Dr. FERGUSSON, whose case it was, considering it as one of imperforate *rectum*, desired I should see the child; and on the evening of this day I saw her. On examination, I could pass my finger up about two inches, but not farther, and the gut seemed to terminate in a blind pouch; no sensation of fluctuation above could be felt; and I therefore did not consider myself justified in passing a trocar, without knowing where it might go; but, being desirous to give the child a chance of life, I determined on making an artificial *anus*. For this purpose I cut upon the *linea alba* about half an inch above the *pubes*, and, opening

---

(*a*) HENKEL, Neue Bemerk., fasc. i. p. 11.

(*b*) ZANG, Darstell. blut. heilk. Operat., vol. iii. pt. ii. p. 436.

(*c*) Archives générales de Médecine, 1835. p. 237.

the *peritonæum*, caught up a portion of small intestine, and having cut into it, fixed the cut edges by stitches to the wound in the *linea alba*. Soon a quantity of *meconium* passed, and continued to do so on the day following; but on the third day she began to vomit bile and frothy mucus, and at 2 P.M. died. On *examination*, the gut was found adherent to the wound. The *colon* was quite empty and contracted to the size of a crow-quill, but it was continuous with the *rectum*, and both intestines were quite pervious. The finger had been prevented passing up the *rectum* by a sudden turn, at which part it was close bound down to the *sacrum*. The *jejunum* and *ileum* were much distended with fæcal matter; and on slitting open the latter, the two portions of the ileo-colic valve were so nearly adherent, that nothing would pass through, although there was a very small aperture.—J. F. S.]

1614. When the *rectum* opens into the *vagina*, a director must, if possible, be introduced through the latter into the *anus*, thrust down vertically, and, when its position has been ascertained by the forefinger, a straight bistoury or a trochar must be thrust through the closed anal aperture, towards the groove of the director, and the puncture afterwards enlarged in the manner described. This practice is, however, generally fruitless, and it is preferable to divide, through the *vagina*, all the parts back into the *rectum*, and by the insertion of lint, or, still better, by the daily introduction of the finger, oiled, to prevent the re-union.

In one case, in which this treatment was in vain, as the artificial opening of the *rectum* closed again, whilst the opening of the *vagina* remained, Barton (*a*) employed the following method with success. He passed a director through the hole of communication in the *vagina*, and divided the whole wall of the *vagina* to the place where the natural opening of the *rectum* should be. He did not use any dressing, but every day passed the finger, smeared with cerate, into the *rectum* to prevent it closing. The *vagina* was perfect, and the *rectum* had a direct opening, except that the stools passed involuntarily. Satchell (*b*) also, and I myself have by this practice obtained like favourable results. Velpeau (*c*) had proposed this operation on the recommendation of Vicq. d'Azyr. After the division is perfected, a canula should be introduced into the *rectum*, fixed towards the hind angle of the wound, by means of which the aperture must be preserved, and the divided parts enabled to unite in front.

Dieffenbach (*d*) introduced a director much bent inwards, through the *vagina* into the aperture of the *rectum*, thrust a pointed bistoury close behind the *fossa navicularis* into the groove of the director, and cut out from thence with the point of the knife, at the same time dividing the whole *perinæum* and widening the aperture of the *anus*, at a single stroke, to near the *coccyx*. The *rectum* was laid bare by the division of the cellular tissue, stretching forwards to the *vagina*, and presenting at the bottom of the wound. He then dissected the edge of the *rectum* from the wound he had made, divided to the extent of an inch in the direction of the external skin and the muscular wound, and fastened the separated edges of the *rectum* on each side of the cleft *perinæum*. The aperture of the *rectum* in the *vagina* closed very completely during the after-treatment by occasionally touching it with lunar caustic. On the complete cure of all the wounded parts, three weeks after the first operation, the formation of a new *perinæum* was attempted. The hind surface of the open end of the *rectum* was farther separated from the *vagina*. The portion of intestine thus set free in the middle, contracted remarkably, and receded about four or five lines. The scar of muscle and skin was removed from the thus formed interstice, the deeper-lying parts were brought together with a needle-stitch, but the edges of the wound with two very short harelip-pins and the twisted suture. The cure was completely successful.

1615. When the *rectum* opens into the *urethra*, a sound must be passed by the latter into the bladder, and the unnatural opening in the *urethra* divided upon it towards the *coccyx*, and with some cautious strokes of the knife the aperture in the *urethra* and the wall of the intestine opposite the place of the *anus* divided. If possible, the sound should be brought through the unnatural opening in the *urethra*, into the cavity of the

---

(*a*) Medical Recorder of Medicine and Surgery. Philadelphia, 1824.

(*b*) Ibid.

(*c*) Elémens de Méd. Opér., vol. ii. p. 979.

(*d*) Ueber die Verschliessung des Afters; in Hecker's Annalen. 1826, Jan. p. 31.

rectum, and such direction given it, that it may be distinctly felt from the *perinæum*, and the covering of the *urethra* divided in the course of the *raphe*, together with the wall of the straight gut opposite the place of the *anus*, or treated according to **Amussat**'s plan (*par*. 1613.)

When the *rectum* opens into the urinary bladder, it is possible for a girl to live, on account of the shortness and extensibility of the *urethra;* but in a boy this malformation is fatal, if the wall of the *rectum*, opposite the place of the *anus* be not open, or an artificial *anus* made.

In a case, in which the *rectum* was imperforate, and opened into the bladder **Fergusson** (*a*) made a cut into the neck and body of the bladder at the place of the *anus.*

[**Cruvelhier** (*b*) gives an instance in which the *rectum* opened under the *glans penis*, by means of a canal which was formed in the substance of the *raphe scroti.* A similar case to this occurred to me, and will be described at the end of *par.* 1617.—J. F. S.]

1616. In all cases, where, by the above-mentioned modes of treatment, opening the imperforate end of the *rectum* is impossible, or when the *rectum* terminates by a blind end in the belly, as also in the not-to-be-overlooked narrowing of the *rectum* by unreachable strictures and the like, some assistance, though not much, may be afforded by the formation of an artificial *anus* at the lower end of the *colon*, (*laparo-colotomia*,) which may be performed in two ways. *First*, A cut from an inch and a half to two inches long is to be made obliquely from behind forwards, so that its lower end should be a little below the upper front iliac spine, and half an inch from it, and continued, layer after layer, through the skin and muscles; the *peritonæum* is then carefully opened, raising it with the forceps, and the sigmoid flexure of the *colon* sought for, drawn to the wound, two waxed threads carried round it, and a longitudinal cut having been made in it, returned into the belly; and, by means of the threads, retained between the edges of the external wound with which it unites (1). *Second*, In order not to wound the *peritonæum*, a cut, three inches in length, must be made, according to **Callisen**'s (2) method, in the left lumbar region, between the iliac crest and the short ribs, on the front edge of the *m. quadratus lumborum*, at which part the descending *colon* lies enclosed in cellular tissue external to the *peritonæum*, and is here to be opened (*c*). **Amussat** makes a transverse cut two inches above the iliac crest, from the outer edge of the *m. quadratus lumborum* to the middle of the iliac crest, through the skin and abdominal muscles, thus cutting across the *m. transversalis* and its aponeurotic layer, then separates the fatty tissue which covers the gut, passes two threads through its wall, to prevent it falling together; then stabs the *colon* with a trocar, enlarges the aperture with the bistoury in several directions, and connects it by four stitches to the front corner of the wound (3).

(1) This operation was proposed by **Littre** in 1720; but first practised successfully by **Dinet** in 1793 (*d*). See also **Freer** (*e*).

(2) This mode was tried by **Roux** without success.

(3) **Amussat** has performed this operation successfully in a woman of forty-eight, and in a man of sixty-two years of age (*f*).

Pilore (*g*) made an artificial *anus* on the right side, by which he opened the *cæcum*

as previously advised by **Benjamin Bell**, and as was to be done in the immobility of the S. Romanum.

The formation of an artificial *anus* has been also proposed in adults, for the not-to-be-overlooked narrowing of the *rectum* from unreachable strictures, and the like. **Freer** (*a*) made a longitudinal cut, of three inches, in the left iliac region, about an inch above the upper front iliac spine, and an inch and a half in front of it, laid bare the *colon* fastened it with two stitches in the wound, and opened it longitudinally to the extent of two inches. The patient died on the *tenth* day. **Pring** (*b*) made a cut obliquely downwards, and inwards two inches above, and an inch on the inner side of, the front iliac spine, to within three-quarters of an inch of **Poupart's** ligament, through the skin and muscles; opened the *peritonæum*, and enlarged it to three inches. The sigmoid flexure of the *colon* was laid bare to the wound. The result was successful.

Compare also **Martland**, a case in which the operation for artificial *anus* was successfully performed; in Edinb. Med. and Surg. Jour., vol. xxiv. p. 271. 1825.

Although in imperforate *anus*, if no assistance be rendered, fatal consequences ensue, in consequence of the stools not being passed; there are, however, instances in which, with imperforate *anus*, and even with accompanying deficient urethral opening, life has been sustained months (*c*), and even years (*d*); in which cases the stools have been vomited by the mouth.

1617. When the *anus*, though not imperforate, is yet congenitally narrowed, the existing aperture must be enlarged by means of a button-ended bistoury and director, and then its reunion prevented by the introduction of lint. This congenital narrowing of the *rectum* may be to such extent, that so long as, during infancy, the stools have little hardness and thickness, it is of no consequence, but as the child grows, and the motions become larger, inconvenience arises (*e*), and the treatment must be such as already mentioned.

[I had under my care, very many years ago, a case of imperforate anus (*f*), similar to that mentioned by **Cruveilhier**. At the time of birth there was not any opening, but a slight puckering marked the place of the *anus*, and this was protruded each time the child cried. In front of the *scrotum*, and in the track of the *raphe*, as it passed on to the prepuce, was a small aperture, just large enough to admit the entrance of a probe, and from it, when the child cried, a small quantity of *meconium* passed. I cut upon the puckered skin, but it was full an inch before the *rectum* could be reached, and I then opened it sufficiently to admit a large urethral bougie, and the *meconium* readily escaped. A probe, introduced at the opening before the *scrotum*, passed along a canal, beneath the *urethra*, through the *perinæum*, becoming larger and larger as it approached the *rectum*, in which it terminated. No bougie, or anything else, was left in, as I thought keeping the bowels loose would have been sufficient to prevent union; however, in the course of a fortnight the wound had closed, and no motion was passed, except by the aperture in front of the *scrotum*. I therefore had to cut into the *rectum* again, and a piece of bougie was then introduced, to be worn constantly, but removed three or four times a-day, for emptying the bowels. This went on very well for a time, but, probably, from negligence, the scar contracted, and at the end of three months the anal opening would not admit even the point of a probe. The scar was, therefore, again divided, and a larger bougie introduced, and worn for a fortnight, after which, a short pewter pipe, about the thickness of the little finger, with a circular shoulder to prevent it slipping entirely into the gut, was introduced, so that the motion might pass continually by it, and the opening be established. Two months after, the pipe having slipped out, and been neglected, the opening had again closed, and again required enlarging with the knife to readmit the tube. The parents' negligence again compelled

the dilatation of the aperture with the knife, and a large bougie was directed to be passed frequently. I did not again see him until he was seven years old, when he was a well-grown boy, but with an enormously distended belly. The *anus* continued open, though not very sufficiently, and the orifice before the *scrotum* was still open, and, occasionally motion passed by it. I was desirous of removing this unnatural canal, but the mother was averse to it, and the child's unhealthy appearance did not lead me to expect that he would live very long. I had entirely forgotten him, when, eleven years after, (he being then eighteen years old,) I was surprised on seeing a fine healthy young man, who said he was the person on whom I had previously operated. The appearance of the *anus* could be compared to nothing else than a bullet-hole in a board: he said he had no difficulty in passing or retaining his motions; but it was quite evident, from his linen, that there was a continual oozing. The opening in front, instead of being near the *frænum præputii*, was now close to the *scrotum*, and a small quantity of stool occasionally escaped from it. On examining more closely, I found the anal orifice completely filled with a protruded portion of the lining of the *rectum;* it, however, offered no obstruction to the finger, which readily passed up as far as the knuckle, and was received into a large cavity full of fæculent matter, and running forward along the *perinæum*, beneath the membranous part and the bulb of the *penis*, to the back of the *scrotum*, where the canal narrowed, and would only admit the finger; with this the opening before the *scrotum* communicated. It was curious, in this case, that although there was an entire absence of the *sphincter* muscle, the stools did not pass involuntarily; the protruded fold of the internal membrane seemed to form a valve which prevented ordinarily the escape of the stool, and compensated the deficiency of the *sphincter*. I proposed to him the removal of the continuation of the bowel into the *perinæum*, but he would not submit to any operation. I have not seen him for the last eleven years.—J. F. S.]

1618. The narrowing of the *rectum*, which takes place in later years, arises either *from spasmodic contraction of the m. sphincter ani*, or *from a thickening, swelling, or degeneration of the mucous or other membranes of the rectum*, or *from swellings in the neighbourhood of the rectum*, or *from large scars*, which have formed near the anal aperture.

1619. The *spasmodic contraction of the anus* is, for the most part, accompanied with a fissure, or with a cleft in the folds of the *sphincter* muscle; though it is, however, seen without either. Adults appear to be almost exclusively subject to this complaint, and women more frequently than men. Its causes are very obscure; it is frequently preceded by hæmorrhoidal congestion, or it occurs after the removal of piles. It is more probable, according to some, that the fissure is produced by the spasmodic contraction, than that the latter is caused by the fissure. From my own observations, however, I hold the contrary opinion.

1620. The disease develops itself very stealthily; at first the motions are accompanied with heat and burning, which, however, gradually subside, and often cease entirely, if the patient take heating drinks, use clysters, and wash frequently with cold water. The sensation of heat and burning soon, however, returns, and continues for a longer time, after going to stool. The relief of the bowels is mixed with blood, the pain increases; aperients, clysters, and cooling diet, indeed, produce alleviation, though only for a short time, and the complaint proceeds in spite of their employment. Going to stool becomes so difficult, that the bowels can often only be forced every forty-eight hours, by a purge, by repeated clysters, or injections thrown up every hour. If the costiveness continue several days, the relief is followed by pain as severe as if a hot iron were thrust into the *rectum;* even convulsions and fainting may ensue, and after the relief of the bowels, there remain pain, shooting, and beating, as in an inflamed part. Every violent effort, the use of too heating food, or food taken in too great quantity, always aggravates the complaint, and the patient, therefore, usually takes but little nourishment. In females, the pain often increases at the coming on of the menstrual periods, and also arises from every exertion, cough, jumping, making water, and the like. Some patients, in this disease cannot sit, whilst others cannot stand. In consequence of this contraction, very large quantities of stool are retained, the pressure of which, against the *anus*, causes long-continued and fruitless straining, and its discharge can only be produced by injections, or by the mucus which the intestine secretes; even the escape of air is often accompanied with pain. When the disease has long continued, wasting takes place from the severity of the pain, and disturbance of the rest, very great sensibility, often hypochondriasis, and affections of the neighbouring organs, as retention of urine.

1621. On examining the external orifice of the *rectum*, hæmorrhoidal tumours or little knots are often found; also, in some cases, a slight discharge, which symptoms, according to Boyer, not in immediate relation with the complaint, on the contrary, are so, according to my experience, as, after the removal of such knots, I have noticed a speedy cure. In those cases in which contraction of the *anus* is accompanied with fissure, the lower end of the latter is found at the part where the patient feels pain, usually in the right or left side of the circumference of the *anus*: in most cases it, however, can only be seen, when the buttock of the affected side is forcibly drawn back, and the anal orifice drawn a little asunder, in many cases, indeed, the fissure cannot, even in that way, be discovered. The introduction of the finger into the *rectum*, which always causes severe and almost unbearable pain, if it press on the fissure, discovers a violent, permanent contraction, but neither swelling nor hardening of the mucous membrane: but at one spot, a lengthy indentation running the length of the intestine may be found; or the fissure is distinguished by the peculiar pain which the patient feels when pressure is made upon it.

[Brodie observes, that, "in connexion with the spasmodic contraction of the *sphincter* muscle, you will frequently find a small ulcer of the mucous membrane of the *rectum*. This ulcer is always in a particular spot, at the posterior part, opposite to the point of the *os coccygis*. I imagine that it arises from the mucous membrane there being torn by the pressure of the hard *fæces*, at the time that the evacuation is labouring, as it were, to get through the contracted orifice of the *anus*. Such an ulcer as I have just described adds very much to the patient's sufferings. It is always excessively sensitive; the least pressure of the finger upon it occasions the patient the greatest pain, and the pressure of solid *fæces* produces the same effect. (p. 26.)

Bushe (*a*) speaks of another form of spasmodic contraction of the *sphincter ani*, in which no primary affection of the gut is discoverable, and in which the introduction of the finger into the gut does not give pain. (p. 126.)]

1622. Spasmodic contraction of the *anus* may be distinguished from its narrowing, by the swelling, and by the disorganization of its mucous membrane, by the pain which accompanies going to stool, and continues some time after, by the absence of discharge of matters, by the long-continuance of the complaint, and by the introduction of the finger beyond the contraction of the *sphincter*, discovering neither tubercle nor hard ring formed by the internal membrane of the *rectum*. The characteristic sign is the fixed pain at one spot of the circumference of the *anus*. It must not, however, be overlooked, that continued spasmodic contraction of the *rectum* gradually causes a greater development and activity of the *sphincter*, as well as plastic exudation, organic changes, and thickening of the gut itself from the constant irritation.

1623. The remedies employed for spasmodic contraction are, cooling

---

(*a*) Above cited.

treatment, the avoidance of all heating food and drink, frequent use of gentle purgatives, and clysters several times a-day, steam-baths of hot water, decoction of chervil, infusion of elder flowers, cold hip-bath, whole or half bathing, application of leeches, narcotic injections, suppositories of *opium, hyoscyamus* and *belladonna*, a dram of acetate of lead, a dram of extract of *belladonna* with six drams of fat, according to Dupuytren's prescription, opiate ointment; also, a salve, composed of equal parts of lard, expressed juice of houseleek, nightshade, and sweet almonds. These remedies, indeed, relieve the patient, but are nearly always inefficient for the cure, and even commonly for assuaging the complaint (1). Any attempts to enlarge the anal orifice with bougies, according to Boyer and others, increases the pain and contraction. Beclard (*a*) has, however, employed masses of lint, of gradually increased thickness, to cure the spasmodic contraction of the *rectum* without fissure. According to Delaporte (*b*) the bougie should be smeared with *belladonna* ointment. He prefers this to cutting, and does not object to touching the fissure at the same time with caustic, by which the pain is suddenly got rid of: he mentions instances in which cutting was of no service. According to Bushe (*c*) all purgatives should be avoided, as they always irritate; a linseed clyster daily, together with careful cleansing of the parts, is preferable. If the disease be slight, the application of lead ointment may be sufficient, and in violent spasm, extract of *belladonna* at the same time. In superficial fissures, lunar caustic should be used, and with it a dressing of lint spread with one part of extract of *belladonna*, and seven parts of *ung. rosat.* (2). According to Pagen (*d*) the parts should be smeared with a mixture of opium cerate and extract of *monæcia;* and Bretonneau (*e*) recommends fomentations of rhatany. I have, in some instances, effected a cure at the beginning of the disease with bougies smeared with zinc ointment, or by its introduction. We should always examine the *anus* very closely, touch every part with the finger, especially every knot, and remove it, if painful. I have ascertained by experience, that spasmodic contraction of the *anus* is more frequently the consequence of seemingly trifling things, than is usually supposed. Similar symptoms are often observed, from the trifling ulcerations, and little excrescences about the female *urethra*, after the cure or removal of which, the most severe symptoms of difficulty in making water quickly subside. I have ascertained that, in such cases, the disease may be got rid of, at first, by the removal of such excrescences, or the cure of the fissure, but which is often useless, if too long delayed till the above-mentioned changes of the *rectum* have occurred (3).

(1) Only in one instance, where the fissure was accompanied with moderate contraction, was the cure effected by Boyer's treatment. I noticed this once in a fissure, with violent contraction and very severe pain, in a woman.

[(2) Brodie objects to the use of the *belladonna*, as, "even in the form of a suppository, it sometimes produces very serious symptoms by its influence on the brain." (p. 26.)]

(3) In one case, in which the spasmodic contraction of the *anus* was accompanied with most severe pain, I found, on examination, a fissure, and with it a very small red knot; I first cured the fissure by frequently touching it with a solution of corrosive sublimate, which gave relief, and then by the removal of the little knots, an immediate cessation of all spasmodic contraction, and a complete cure ensued.

1624. The surest mode of getting rid of the contraction, either with

---

(*a*) Bulletin des Sciences Méd., 1825, p. 199.

(*b*) Révue Médicale, vol. ii. p. 110. 1830.

(*d*) Gazette Médicale, vol. viii. p. 59. 1840. No. 4.

(*e*) Trousseau; in same. No. 36.

or without fissure, if it withstand the previous treatment, is, to cut into the edge of the *anus*, either at the seat of the fissure or at any other part. The patient should take a mild purgative three days before, and on the morning of the operation a clyster to empty the bowel, and to avoid the necessity of going to stool for some days. He should be laid upon his side, as in the operation for *fistula in ano*, the forefinger of the left hand, oiled, passed into the *rectum*, and a narrow, button-ended bistoury introduced flat upon it, the edge of which being turned to the side on which the fissure is, cuts through with a stroke the intestinal membranes, the *sphincter* muscle, the cellular tissue, and common teguments, forming a triangular wound, the apex of which corresponds to the cavity of the bowel, and its base to the external skin; sometimes a lengthening of the latter is requisite, which must be done with a second stroke of the bistoury. If, by the escape of the bowel from the edge of the knife, the wound in the cellular tissue be higher than in the intestinal membranes, the latter must be further divided with the knife or with blunt-pointed scissors. In very violent contraction of the *anus*, two cuts may be thus made, one on each side, and if the fissure be before or behind, it is not to be included in the cut. The success of this operation is often very surprising.

1625. The dressing consists of a pretty thick plug of lint between the edges of the wound, upon which some wadding and an oblong pad should be applied, and the whole fastened with a T bandage. Bleeding but rarely occurs, and is easily stopped by a slight pressure. After three or four days, the first dressing is to be removed, and replaced daily till the cure is completed, which happens in about four or six weeks. WALTHER rejects the introduction of lint and the like as useless and painful.

1626. The *narrowing of the rectum, depending on chronic inflammation and incipient degeneration of its mucous membrane*, is always of slow production. At first there is a troublesome itching in the bowel, and a secretion of muco-purulent fluid. By degrees the patient is attacked with frequent inclination to go to stool, when he strains much and passes only hard motions, of thinner size than usual: there is a sensation of fulness in the course of the *colon*, but especially in the region of the sigmoid flexure; going to stool becomes more painful and difficult, digestion fails, frequent belchings occur, with occasional severe colic; the collection of stool is often so great that the belly becomes swollen, and inflammation ensues. Frequently, if the narrow part be high up, and the bowel below have lost its expulsive power, the stools squeeze through the stricture in little pieces, collect beneath it, and are discharged in the ordinary sized masses. If *diarrhœa* occur, the patient usually feels more easy. In rare cases there is *diarrhœa* throughout the whole course of the disease; these are of the worst kind, as ulceration is going on simultaneously in the upper part of the intestinal canal.

1627. The disease proceeds more or less quickly according to the difference of constitution; the general health is sometimes affected early, sometimes remains for a long while undisturbed. As the narrowing increases, the costiveness becomes greater, the belly harder and fuller; the digestion becomes more affected, the colic more frequent and severe, and the feet swell. From the continuing costivenesss, fæculent vomiting, as well as quickly fatal inflammation of the belly, or perforation of the intestine above the stricture, may ensue, especially if kernels or other foreign bodies remain sticking in the stricture, and completely close it. If there be perforation, it usually occurs close to the stricture, at one part softened by inflammation, at which the stools are rarely poured forth into the cavity of the *peritonæum*, but rather into the cellular tissues surrounding the *rectum*, and gangrenous abscesses form around the *anus* and on different parts of the buttocks. When these burst, or are opened, a quantity of fœtid ichor and motion burst forth, a large part of the coverings becomes gangrenous, and the patient dies quickly, or *fistulæ* form, and the person may live some time in a lamentable condition.

The stricture may run on to ulceration; severe pain, ichorous discharge, and even bleeding then occur; all assume a carcinomatous character; the destruction attacks the neighbouring parts. *fistulæ* form, the skin about the *anus* and on the buttocks, the urinary bladder, the *vagina*, and womb, are attacked with ulceration; and when the destruction has extended far, the stools cannot be retained, but pass involuntarily, and the patient dies exhausted.

[" In some instances," Brodie states, " the patient dies with symptoms of strangulated *hernia*; that is, a piece of hard *fæces* is lodged above the stricture and cannot pass through it; thus there is a mechanical obstruction to the passage of the *fæces*; the belly becomes tympanitic, the tongue dry; there is sickness, vomiting, and the other symptoms indicating strangulation. He may have one of these attacks, and by means of injections and the use of a bougie, may recover; he may have a second, and recover from that; and then he may have a third, which may prove fatal." (p. 28.)

Astley Cooper (*a*) used to relate the case of a woman who, labouring under stricture of the *rectum*, was obstinately costive. On examination, a plum-stone was found to have lodged just above the stricture; it was removed with stone-forceps, and she recovered.]

1628. By the chronic inflammation, which causes stricture of the *rectum*, the mucous membrane, the cellular tissue beneath it, and afterwards all the other membranes, are thickened, till at last the whole gut is affected. The changes which the inflammation produces, are either its conversion into a hard, fibrous, even cartilaginous tissue (1) or into scirrhous degeneration, or into ulceration, with or without fibrous, cartilaginous, scirrhous, or œdematous degeneration, or into the formation of fungous loosenings, sarcomatous excrescences (2), or into shrivelling and contraction of all the parts at once, so that this part of the gut is diminished to the size of a quill, and its cavity often completely disappears.

[(1) Brodie says:—" On dissecting a simple stricture of the *rectum*, I have found the mucous membrane thickened, of a harder structure than natural, and the muscular tunic thickened also. The stricture sometimes occupies the whole length of the gut,

---

(*a*) MS. Lectures.

for some way up, above the *anus*, perhaps three or four inches; at other times it is only of short extent." (p. 28.)

(2) This, I presume, is the condition to which **Lawrence** (*a*) refers, where he speaks of "another form of disease, (stricture of the *rectum*,) in which the mucous membrane seems to be formed into a large, spongy, soft, excrescence, in which the patient was affected with all the symptoms that would be produced by stricture; for this spongy state of the membrane diminished the dimensions of the bowel." (p. 855).—J. F. S.]

1629. These changes have either a less or a greater extent; commonly, they are circular, and the narrowing is so considerable, that an aperture, not larger than a straw, alone remains; often they occur only at one side or on the edge of the *valvulæ conniventes*, in consequence of which cord or bridge-like contractions, single, cone-like growths are produced. These growths, of different size, attached with narrow necks or by a broad base, soft, hard, spherical, oval, single, and vegetating sparingly, or growing luxuriantly, collected in wide or thick groups, are often confined to the edge of the *rectum*, or spread over the whole extent of the cavity of the *rectum*, or even extend into the *colon*. Although at first insensible, they grow, become painful, and terminate in cancerous ulceration, as already described. The distinction between these excrescences and the hard, hæmorrhoidal knots consists specially in their yellowish red colour, their smooth-skinned, even, tense surface exhibiting not the slightest trace of blood-vessel, in their regular, firm, in some degree elastic consistence, in the absence of all fluctuation, and in their complete insensibility on great pressure. The various form and condition of these hardenings depend on the seat, extent, and character of the inflammation and irritation.

See further on this subject,

Dessault, Squirrhosités du Rectum, in his Œuvres Chir., vol. ii. p. 422.

Schreger, Ueber tuberculöse Excrescenze; in his Chirurg. Versuchen, vol. i p. 258.

Tanchou, above cited.

1630. Stricture of the *rectum*, from the above-mentioned changes of its membranes, may happen at all parts of the bowel, but most frequently in the region of the internal *sphincter*, about two or three inches above the *anus*. The knowledge of stricture of the *rectum*, its seat, nature, and form, is simply and alone to be obtained by examination. On the introduction of the finger, oiled, a narrow, hard, unyielding part is felt, either as one or several little, projecting folds or partitions, into the opening of which the finger can be introduced only with difficulty or pain, or not at all; or as a hardening and contraction of the walls of the gut to a great extent; or as ulceration, with hard edges; or as tumours of various form. The examination should be always made in the recumbent posture, because the valve-like narrowings at the upper part of the gut, which mostly are seated on its front, form a sort of pouch in front, and above the narrowed part, which, when the patient stands upright, prevents the examining finger discovering the stricture. If the narrowing be so high that the finger cannot reach it, the examination must be made with a wax bougie or a sound covered with modeller's wax, which, softened and oiled, should be carefully introduced into the *rectum*, and gently pressed on the seat of stricture, in order to take an impression of it. In doing this, the anatomical relations of the *rectum*, and the rules subsequently laid down for the introduction of the bougie, must be remembered, to prevent mistake, as the examination by this mode is much less certain

---

(*a*) Lectures; in Lancet, vol. ii. 1829–30.

than with the finger. Particular instruments, used for examining strictures of the *rectum*, a stem with a ball, as recommended by **Howship** and **Calvert**, are to be set aside, if the finger can reach the stricture. When the symptoms lead to the supposition of stricture of the *rectum*, the examination should always be made as soon as possible, in order to discover the disease in its earliest stage of development.

[**Lawrence** (*a*) observes:—"We cannot, however be certain that stricture of the *rectum* is the cause of any of the symptoms under which a patient labours, unless we have the power of *feeling* the contracted part of the gut with the finger, or of ascertaining its existence by an instrument, a *rectum* bougie, introduced there: and indeed we can hardly get clear evidence of the fact, when stricture is higher up in the bowel than we can reach with the finger; for you will recollect that the course of the *rectum* is by no means straight, and the surface of the intestine is not smooth and uniform; in its natural state there are folds and irregularities which present obstacles to the passage of an instrument along it. * * * In all instances, therefore, when the disease of the bowel is situated higher up than you can reach with the finger, the evidence is more or less uncertain, unless the difficulties in the evacuation of the *fæces*, or the peculiar configuration and diminished size of them should be well marked." (p. 856.)

Bushe (*b*) remarks, that "organic stricture (of the *rectum*) is supposed by many to be of very common occurrence, but I have not found it to be so; for the cases I have seen bore no proportion to the number I ought to have met with, were the statements made in books correct." (p. 264.)

There has been much said and written as to the usual seat of stricture of the *rectum*; it has been said to be most common about the termination of the *colon* (**White**) (*c*), or five or six inches from the *anus*, and next in frequency at the junction of the sigmoid flexure of the *colon* with the *rectum*. (**Salmon**) (*d*). These, however, must be very rare cases, for all the best authorities declare the stricture to be almost universally low down. **Charles Bell** (*e*) says:—"Not unfrequently, the inner edge of the deep *sphincter ani* being the seat of this stricture; and then the finger only enters to the depth of the second joint, when it is obstructed by a sort of membrane standing across the passage. Sometimes the stricture is more than two inches within the *anus*, and feels like a perforated *septum*." (p. 330.) **Colles** (*f*) says:—"In a few instances the stricture has been seated so high up in the gut, that it could be but barely touched with the point of the finger, until the patient was desired "to force down," and then a satisfactory examination of it could be made." (p. 139.) According to **Allan** (*g*), "stricture of the rectum most commonly occurs near the termination of the gut, a little within the *sphincter*, but it may take place in any part of the *rectum*, sometimes the whole gut is lessened in diameter, and on other occasions the stricture is situated in the sigmoid flexure of the *colon*." (p. 488.) **Liston** (*h*) speaks of it as "readily ascertained by examination with the finger." (p. 73.) And **Syme** (*i*) that "it is generally found at about two and a half or three inches distant from the orifice, but may be situated much higher up." (p. 445.) **Brodie** (*k*), in speaking of these strictures, says they "are commonly situated in the lower part of the gut, within the reach of the finger. Are they ever situated higher up? I saw one case where stricture of the *rectum* was about six inches above the *anus*, and I saw another where there was stricture in the sigmoid flexure of the *colon*, and manifestly the consequence of a contracted cicatrix of an ulcer which had formerly existed at this part. Every now and then, also, I have heard from medical practitioners of my acquaintance of a stricture of the upper portion of the *rectum*, or of the sigmoid flexure of the *colon*, having been discovered after death. *Such cases, however, you may be assured, are of very rare occurrence.* Inquire of anatomists who have been for many years teachers in the dissecting-room, or of Surgeons who have witnessed a great number of examinations in the dead-house of an hospital, and they will bear testimony to the correctness of what I have now stated. Nevertheless, an opinion has of late years prevailed among some members of our profession, that a stricture high up in the *rectum* is a very frequent cause of constipation of the bowels; and I have known an almost incredible number of persons who have been treated on the supposition of their labouring

under such a disease, by the introduction of long bougies into the bowel. The only evidence of the existence of a stricture in these cases has been, *first*, that there was obstinate costiveness; *secondly*, that a bougie introduced into the *rectum* could not be made to pass beyond a certain number of inches beyond the *anus*. But what is the value of this evidence compared with that which anatomy affords of the rarity of this kind of stricture? Are there not many causes of a costive state of the bowels, besides mechanical obstruction? Will it be always easy, even in the most healthy *rectum*, to introduce a bougie more than a few inches into it? Although we call the lower bowel the *rectum*, you know very well that it is anything but a straight gut. Three or four inches above the *anus*, the *rectum* begins to make flexures, which increase as you trace it upwards, until they terminate in the sigmoid flexure of the *colon*. These flexures of the *rectum* differ in different individuals, and even in the same individual, at different periods. When a bougie is introduced, be it small or large, it is certain that it will be stopped somewhere or another by one of these flexures; and nothing can be more unphilosophical than to conclude, because a bougie meets with an impediment at the distance of five or six, or eight or nine inches, that this is the result of an organic disease of the *rectum*, when the natural formation of the parts will sufficiently account for it. But let us suppose that you actually meet with one of those rare cases in which there is a stricture in the upper part of the *rectum*; by what means are you to recognise the disease in a living person? Or if you can recognise it, how can you know its exact situation? If the bougie can only be introduced to a certain distance, how are you to be certain that it is stopped by the stricture, and not by a fold of the bowel, or even by coming in contact with the *sacrum*? Further than this, if you employ the force which you would suppose to be necessary to make the bougie penetrate through the stricture, is there no danger of penetrating the tunics of the intestine instead? This last is no theoretical objection to the use of these long bougies in diseases of those parts. I will not say that I have seen the patients; but I have been informed on good authority, of not less than seven or eight cases in which this frightful accident occurred, and the patients died in consequence." (p. 30.) Lastly, BUSHE states:—"Independently of the malignant forms of disease hereafter to be described, I have very seldom seen a contraction of the *rectum* which was not within the reach of the finger." (p. 265.) I am afraid that the conclusion of one of his notes is not without its parallel in this country, and ought to be held up to the reproof it richly deserves. "I am mortified to add," says he, "that I have good reason for supposing there are a few who make a profitable trade of treating dyspeptic patients for stricture of the *rectum*, asserting that the obstruction is high up, when in truth, this intestine is perfectly free from structural disease. Such practitioners, by passing bougies, apparently cure, what in reality never existed, and thus obtain a character for skill in the treatment of this disease, which in truth they do not possess."—(p. 266.)

1631. The immediate cause of stricture of the *rectum* is always a more or less extensive inflammation or continual irritation of the *rectum*, in consequence of which there is secretion of plastic matter, thickening and degeneration of the tissue. The *causes* are, hæmorrhoidal affections and abdominal *plethora*, anomalous gout, *syphilis*, metastasis of skin diseases, suppression of the usual discharges, frequent indigestion, badly treated irritation of the intestinal canal, *diarrhœa*, improper use of irritating purgatives, constant costiveness, injury of the *rectum* by foreign bodies, extirpation of hæmorrhoidal knots, operation for *fistula in ano*, and pædarasty, as I have witnessed in two instances.

1632. The *prognosis* differs according to the degree, condition, seat, and cause of the stricture. Membranous, circular, and strictures unattended with ulceration, if not seated high up, lead to a favourable *prognosis*. If the disease be more advanced, the stricture accompanied with much hardening, seated high up, and its causes cannot be removed, the *prognosis* is unfavourable; perhaps by cautious treatment temporary relief may be obtained, but never a perfect cure. If the stricture have run on to ulceration, the patient, generally, can scarcely obtain relief, and any treatment not especially cautious, renders him worse, and hastens the evil results. The same happens in carcinomatous degeneration.

[Brodie observes, that "success in the management of this disease will vary very much in different cases. It will depend chiefly on the period of the disease on which you are consulted. If it be quite in the early stage, you may render the patient great service; and although you cannot cure the stricture of the *rectum*, any more than you can cure the stricture of the *urethra*, yet you can dilate it, and keep it dilated, so that the patient will suffer little from it, and that it will not shorten his life. But if you are consulted in the advanced stage, when the stricture is much contracted, when the mucous membrane is ulcerated, when abscesses have formed in the neighbourhood, you can only palliate the symptoms in some degree. The patient under the circumstances, in spite of all your efforts, will lead a a miserable life, and in all probability will ultimately fall a victim to the disease." (p. 30.)]

1633. The *treatment* of stricture of the *rectum* consists in subduing its cause and the constitutional disease in causal relation to it, and in the removal of the stricture. The first indication requires the use of suitable antiphlogistic remedies, or such as operate on the skin, purging, proper treatment of hæmorrhoidal affections and abdominal *plethora*, and so on; but especially strict attention to the mode of living, carefulness as to free relief from the bowels, repeated application of leeches, soothing injections into the *rectum*, hip-bath, rubbing in mild ointments with, according to circumstances, extract of *belladonna* or *cicuta*. By such treatment, with proper care, and corresponding to the circumstances of the individual case, a stop may be put to an incipient stricture, as I have in some instances observed. I have also used at the same time, internally, iodide of potash with good effect. But such result is only possible in the very beginning of a stricture; if it have already proceeded farther, no effect can be produced on the stricture itself, but it is necessary, if the stricture and the *rectum* be in a state of irritation, to undertake in addition the direct employment of mechanical remedies upon the stricture, which consist of *stretching*, *cutting into* or *cutting out*, and *cauterization* of the stricture.

["In some cases," says Brodie, "the *fæces* accumulate above the stricture, the bowel, in this situation, becoming distended into a large bag, forming an immense reservoir of fæculent matter, always pressing against the stricture, and aggravating the disease. It is very important to empty the bowel which is thus loaded; and you can only do it in the following manner:—Introduce an elastic gum catheter through the stricture into the fæculent mass above; inject tepid water, or tepid soap and water, or a weak solution of caustic alkali; and by repeating this operation, and washing out the gut with warm water every day, or every other day, you may at last get the whole of the fæculent accumulation dissolved, and empty the reservoir. When this has been accomplished, the injection of warm water should be constantly repeated, so as to prevent the accumulation taking place again." (pp. 29, 30.)]

1634. *Stretching*, by which the narrowed part may be enlarged, and the consolidation of the cellular tissue accompanying it overcome, is effected, with plugs, wax, and elastic bougies, sponge tent, with metallic, linen, or goldbeater's skin dilators, and the like.

1635. The plugs of lint which Desault used with the especial object of introducing medicated substances, are carefully passed into the stricture with a plug-holder, after having been smeared with mild ointment, to which extract of *belladonna*, or *cicuta* have been added; or an injection of decoction of *cicuta* is made. The plugs should be made thicker, and allowed to remain up for a longer time, according as the patient can bear them. As their introduction with the holder is often difficult, and the plug completely closes the *rectum*, so as even to prevent the escape of air, Tanchou has proposed fixing the plug on an elastic metal canula, and to introduce it on a silver button-ended probe, first passed into the stricture.

1636. Elastic and wax bougies, of corresponding size, are introduced into the stricture. Properly prepared wax bougies, of from one to three and half inches in circumference (SALMON) are the best. In introducing these bougies the following rules are to be observed, according to the different heights at which the stricture is situated. The bougie, curved according to the curvature of the *rectum*, and well oiled, with the convexity corresponding with the first curve of the gut, and directed towards the *sacrum*, is thrust in upwards and backwards, in this direction, to the extent of two inches. After a little waiting, the bougie is introduced still higher, from three to three and a half inches above the second curve of the *rectum;* the inner extremity of the bougie still remains in the hollow of the *sacrum*, and the outer end is inclined to the left side. If the bougie be introduced still further, its direction must be changed, the outer end being raised from left to right in a semi-circle, and pushed forwards at the same time, and in this manner it may be introduced yet four inches further. If the instrument have to be passed into the sigmoid flexure its outer end must be pressed gently down, and pushed upwards, till it be completely carried in. The deeper the instrument is introduced the more care must be taken, lest dangerous irritation, or even perforation, of the sigmoid flexure should occur. There is, commonly, pain over the whole belly, and violent forcing. The contraction of the *sphincter* causes the most difficulty; the bougie, therefore, of different length, according to the seat of stricture, is to be well passed into the *rectum*, and there retained by means of a bandage attached to it. The patient should keep quiet in bed, and the bougie allowed to remain in, not longer than from six to ten minutes, nor so long, if the patient complain of severe pain. Its introduction is to be repeated every two or three days, its size increased, as also the time it should remain, according to the patient's irritability, but every violent irritation should be carefully avoided. I have used elastic bougies with a dilator, as in narrowings of the *œsophagus*, (*par.* 1606,) which I once introduced into a stricture, and repeated every two days, as dilatation, continued, for some time, easily sets up considerable iritation, and even becomes unmanageable. In strictures, situated high up in the *rectum*, the elastic or wax bougies are the only remedies which can be employed.

[BRODIE observes:—" In a great number of cases, where the disease is far advanced, you cannot resort to the use of the bougie in the first instance, or, if you do, it must be employed in combination with other remedies. It will be necessary to lessen the irritability of the bowel by the introduction of an opiate suppository every night, and a gentle aperient taken in the morning. The patient may take a combination of caustic potash with copaiba; half a dram of balsam of copaiba, fifteen minims of *liq. potass.* three drams of mucilage of gum arabic, and about nine drams of carraway water. A draught of this composition may be taken three times a-day with very great advantage. BRYANT, of Edgeware-road, recommended to me a decoction of *Achillea millefolium*, which I have employed in some of these cases with manifest advantage. About two ounces of the *Achillea* may be put into a pint and a half of water and boiled down to a pint, of which the patient may take a wine-glass full three times a-day." (p. 29.)

With regard to the use of bougies in stricture of the *rectum*, LAWRENCE says:—" It is a question how far the stricture can be relieved by the introduction of bougies. When the stricture is situated so near to the *anus* that you can examine it with your finger, and when you can, therefore, ascertain with considerable certainty something of the state of the bowel, when you can ascertain, by such means, how far the mechanical irritation of dilatation will be borne, you may cautiously use bougies, as in the case of stricture of the *urethra*, but you must employ them under the same kind of restrictions and cautions as in that case. Indeed, you may find it necessary to be even more cautious in the case of the *rectum* than in that of the *urethra*, inasmuch as you are so much uncertain, when you meet with a difficulty, whether you are pressing against strictured or sound parts of the gut. You must employ instruments which will not be likely to injure the bowel.

Very commonly you find instruments of elastic gum recommended for this purpose, which have the advantage of being sufficiently smooth, but they do not readily accommodate themselves to the course of the canal: I do not consider them eligible instruments. Therefore you had better use *rectum* bougies, made of a soft composition; and, I consider, indeed, that the common plaster bougies, used for the *urethra*, are not of a sufficiently soft substance for a *rectum* bougie. There are *rectum* bougies, made for the purpose, of a composition so soft, that if you dip them into tepid water, they will be immediately softened, and very well adapted for the purpose. These are what I would recommend; and you should never employ any force."* (p. 856.)

"In some cases of stricture of the *rectum*," Brodie says, "I have thought that the patient has derived benefit from the application of mercurial ointment to the inside of the gut, which is easily managed in the following manner. Let the bougie be covered with lint smeared with mercurial ointment; the bougie, thus anointed, must be allowed to remain in the stricture for a few minutes daily." (p. 30.)]

1637. For the purpose of increasing the extension at pleasure, and to operate specially upon the narrowed part, peculiar dilators have been proposed by Arnott, Bermond, and Costallat. Arnott, as well as Charles Bell, introduces a piece of prepared gut, by means of a sound, into the stricture; the distension of the former is effected by blowing in air, and of the latter by injecting water. Bermond's (*a*) and Costallat's (*b*) apparatus consists of a little bag of linen or gold beater's skin, introduced into the stricture, and by filling it with lint, extension can be made specially at the seat of the stricture. The constant distension purposed by these apparatus easily excites violent irritation and pain which is unbearable.

1638. In the dilatation by metallic means, as the dilators recommended by Weiss and Charriere, for which also Astley Cooper employed a pair of narrow forceps, the distension is effected gradually, and repeated in a few days. Astley Cooper (*c*) in this way established the calibre of the bowel in course of a few weeks, in two instances. Dilatation with metallic instruments can only be employed in valvular and recent strictures which are not complicated with hardening or inflammation.

1639. Cutting into the narrowed part, generally objected to by many Surgeons, can be employed only in valvular or circular strictures which can be reached with the finger, and are unconnected with inflammation, hardening, or hypertrophy. In hardening, and in carcinomatous degeneration it always produces bad symptoms. A button-ended bistoury is to be carried in upon the introduced finger of the left hand, or upon a director, and the bridges divided with it, or several notches made in the stricture, at proper distances apart from each other or at the most projecting part. If possible these cuts should be made towards the *sacrum*, and always with care not to extend beyond the bounds of the disease, nor to cut open the walls of the bowel itself.

Wiseman (*d*) first made use of such cuts in stricture of the *rectum*.

Copeland (*e*) says:—"In the indurated annular stricture, which has for a long time resisted the introduction or the enlargement of the bougie, I have more than once introduced a probe-pointed curved bistoury, and divided the thickened parts, on that side of the *rectum* which is contiguous to the *sacrum*; and I have frequently seen the late Mr. Ford perform the same operation. Wiseman divided a contracted gut three or four times in the same person; his case, however, was not one of idiopathic stricture, but was produced by the rude operation for *fistula in ano*, which was practised at that time." (p. 32.)

(*c*) Tanchou, above cited.

(*d*) Several Chirurgical Treatises, p. 239. London, 1676. fol.

(*e*) Above cited.

[**Brodie** recommends the division of the stricture, in the following manner :—"Introduce a *bistouri caché*, and let the screw be so adjusted that the blade may be opened about the sixth of an inch, but certainly not more than a quarter of an inch. The bistouri must be introduced with the blade shut; then press on the handle, open the blade, and drawing it out, you nick the stricture first in one part of its diameter, then in another, and then in a third. This being done, a larger bougie may be introduced than could be done before, and the cure is very much expedited." (p. 29.)]

1640. Extirpation can only be employed in narrowings of the *rectum* dependent on tuberculous excrescences, when situated at the edge or in the lower part of the *rectum*, from whence they may be drawn forth, or protruded by straining at the anal aperture, and being held with forceps or by a thread passed through them, may be removed from their base with knife or scissors without danger. **Schreger**, from experience, prefers extirpation in such cases, although it had been objected to by **Desault**. If the excrescences be seated higher, extirpation can only be performed under certain conditions as to their form, that is, when they are provided with a neck. No important symptoms follow this operation, as the absence of vessels in these excrescences and their insensibility prevent bleeding, and sympathetic affection of the *rectum*, and the internal coat readily shoots over. If the excrescences be situated higher than we can venture without danger to extirpate them, the removal of those nearest the anal orifice will, however, relieve the patient's condition; the application of pressure sufficient to efface those above facilitates, and considerably shortens the cure.

Compare **Rognetta** (*a*) in reference to those warts of the *rectum*, which in their tissue precisely resemble warts on the skin, and must be removed though they frequently return.

1641. Cauterization with a bougie armed with lunar caustic has been employed by **Home** (*b*) in ring-shaped stricture of the *rectum*, and cauterization with dilatation by **Sanson**, in three cases, though without particular effect. (**Tanchou**.) **Sanson** has recommended a caustic-holder similar to that of **Ducamp**; **Tanchou** employs an elastic catheter, opened at the side, into which he introduces a second fitted with caustic. Cauterization must always be considered a very uncertain mode of treatment: it can only be of use when properly performed, and the dilatation is sustained (*c*).

1642. If, in the course of this disease, fistulæ form about the *rectum*, the treatment must first be directed towards the stricture, and when that is got rid of, the fistula may be treated in the usual manner.

If the disease be cancerous, alleviation only can, in most cases, be obtained by thin plugs, smeared with softening and soothing ointments, by injections of decoction of *cicuta*, suppositories of *hyoscyamus*, *belladonna*, and the like. But, if the disease be seated at the lower part of the *rectum*, if its upper boundary can be reached with the finger, if the cellular tissue surrounding the lower part of the gut be healthy, the bowel movable and permitting its drawing down, the extirpation of the cancerous part, according to **Lisfranc**'s (*d*) proposal, may be undertaken.

1643. The patient being placed as in the operation for the stone, two semi-circular cuts should be made about an inch in front of the *anus*, which, dividing the parts to the cellular tissue, should meet behind. The intestine is then to be dissected from its connexions till it is completely

---

(*a*) Gazette Médicale, vol. iv. p. 387. 1836.

(*b*) Practical Observations on the Treatment of Strictures of the Urethra, &c., vol. ii. p. 418.

(*c*) **Tanchou**, above cited, p. 182.

(*d*) Révue Médicale, vol. iii. 1830, p. 471.

set free all round. The forefinger, half bent, is now to be introduced into the gut, and sufficiently drawn down to make the mucous membrane protrude, so that a portion of it can be easily removed with curved scissors, or with the knife. If the cancer affect the whole thickness of the intestinal wall, and do not extend more than an inch upwards, the whole gut must be everted, and the entire disease laid bare. The everted part is then to be cut into, parallel to the axis of the trunk, and cut off with the curved scissors. Should the cancer have affected all the membranes of the intestine and the neighbouring cellular tissue, then after the first two cuts have been made, and the lower part dissected, a cut must be made with a pair of straight scissors upon the introduced forefinger, through the whole wall of the intestine backwards, where few vessels and the *peritonæum* can be wounded, and which has also the preference of rolling out the gut and laying bare the disease at the same time, after which it is to be removed with scissors in the sound part. In operating on men, a catheter must be kept in the bladder, to prevent injury to it. The bleeding vessels must, as far as possible, be tied, or sponge dipped in cold water, or a sufficiently thick bundle of lint introduced. If the bowel have been plugged, the plug must, after some hours, be renewed. For the purpose of preventing the narrowing of the gut whilst the scar is forming, a pretty large bundle of lint must be introduced, and there kept, during suppuration, for a month.

This operation is more difficult in the female than in the male, and an assistant must keep his finger in the *vagina* to prevent its injury, whilst the operation proceeds. In the female, after an oval cut is made, distant about three quarters of an inch from the opening of the *rectum*, and continued to the gut, the *rectum* must be gently pulled, and two inches of its side and hind part removed, without injuring the *vagina*. The projection which the *rectum* forms in front is about sixteen lines, on account of the connexions it has with the *vagina*, which, formed of an aponeurotic tissue, and very thick cellular tissue, stretches through the muscular fibres from the fatty tissue beneath the skin, at a depth of three lines. When, in the female, the *rectum* is dissected up to the attachment of the *peritonæum*, and drawn by means of a pair of forceps, there is a space of six inches forwards, and aside between the lower end of the bowel and the *peritonæum*, but behind we may proceed still higher, on account of the *meso-rectum*. In the male, the distance from the *anus* to the *peritonæum* is about four inches.

1644. When the narrowing depends on a large scar, nothing more can be done than to cut deeply into it at several places, and to widen the anal aperture by the introduction of plugs, lint, or sponge. In the narrowing of the *rectum* by tumours in its neighbourhood, which impress it, the *prognosis* and treatment are guided by their situation and condition.

A narrowing of the *anus* by growing together of the buttocks, as the consequence of badly treated ulceration, so that the motions are only as thick as a feather stem, and for the most part involuntary, RUST (*a*) cures completely by division of the united buttocks.

1645. If narrowing of the *rectum* run on to closure, and *ileus* be produced, the formation of an artificial *anus* is required, although always a very doubtful remedy (*par.* 1616.)

IX.—OF GROWING TOGETHER AND UNNATURAL CLOSURE OF THE PREPUCE.

1646. The unnatural narrowing of the prepuce, so that it cannot be readily retracted over the *glans penis*, is called *Phimosis;* and if the very narrow prepuce which has been retracted cannot be again brought forward, it is named *Paraphimosis.*

1647. *Phimosis* is either a vice of the first formation, and congenital, or it may be accidental, from inflammation of the *glans* and prepuce; in which latter case it is named by some *complicated phimosis*, in opposition to the first form.

1648. The prepuce, in children, has generally so narrow an aperture, that it cannot be retracted over the *glans;* and peculiar symptoms may occur if this aperture be very narrow or entirely closed. When, for example, the orifice of the prepuce is smaller than that of the *urethra*, the urine cannot flow in its usual stream, part of it collects under the prepuce, distends it, and can only be completely voided by pressure. By the urine thus retained, and becoming putrid, the prepuce is inflamed, often lengthens and becomes hard; and even stony concretions may be formed between the *glans* and the prepuce. If the prepuce have not an opening, it becomes distended by the collecting urine to an oval transparent swelling, and the retention of urine may be fatal, if assistance be not afforded in proper time.

1649. If the congenital narrowing of the prepuce be not so great as to produce the just mentioned symptoms, it is rarely noticed before puberty. If the erections of the *penis* then occurring be not sufficient, by degrees, to enlarge the aperture of the prepuce, so that it can be easily retracted over the *glans*, which depends on the great length of the prepuce or the shortness of the *frænum* connecting the prepuce and *glans*, or it may be on the imperfect development of the *penis* itself, erection and connexion will be painful; inflammation, excoriation, and so on, will be produced by the obstructed flow of the urine, and by the collection and putrifying of the cheeselike matter beneath the prepuce; and also the proper ejection of the *semen* will be prevented by a very small orifice of the prepuce.

1650. *Accidental phimosis* arises from inflammation, in which, as consequence of swelling of the prepuce, its aperture contracts, and, as consequence of increased determination of blood, the *glans* itself enlarges. Usually, those persons are attacked with accidental *phimosis* who have, from birth, a very long and narrow prepuce. The special causes may be, venereal ulcers, when seated on the edge of the prepuce, upon the *corona glandis*, or on the *frænum*, internal or external *gonorrhœa*, warty excrescences, and excoriation of the prepuce from putrescence of the cheese-like matter retained beneath it, or from any other irritant. The inflammation is either acute or of an erysipelatous kind; often is the prepuce swollen with *œdema.* *Phimosis* may also be produced by any chronic swelling and thickening of the prepuce, as in hardening, in scirrhous or any other degeneration.

1651. The symptoms caused by such *phimosis* vary according to its degree and its cause. In venereal ulcers upon the *corona glandis,* if the pus be retained, the prepuce may be gradually eaten through, and the whole *glans* often protrudes through the hole. The inflammation may run on to gangrene, which is particularly to be feared in adults, and if mercury have been previously and frequently used; the urine collected beneath the prepuce may cause excoriation, may be effused into the cellular tissue of the whole *penis,* and producing gangrene, cause its destruction. The swelling may even be so great that the *glans* and *urethra* may be partially compressed. If the inflammatory stage pass by, a chronic *phimosis* may remain, in which there is a hard, cartilaginous swelling of the prepuce, or growing together of the prepuce and *glans.* Should the obstruction to the voidance of the urine by the narrowness of the prepuce, affect the bladder and *urethra,* distension, weakness, and even palsy of those parts may be produced.

1652. The *treatment* of *phimosis* consists in removing the narrowing by operation; or in *phimosis,* accompanied with inflammation, by remedies capable of diminishing the swelling of the prepuce and *glans.* In children this operation is only called for when there is complete closure of the prepuce, or the congenital *phimosis* is to such degree that it prevents the discharge of the urine, and in adults, when, besides the voidance of the urine, the discharge of the *semen* is also stopped, connexion painful, or if the orifice of the prepuce have a cartilaginous ring.

If the narrowing of the prepuce be only slight, softening rubbings-in, bathing, and repeated daily attempts to retract the prepuce, are sufficient to widen its orifice (*a*). Particular instruments have been also used for this purpose (*b*). This practice is, however, always tedious, painful, and can only in a few cases be effective.

1653. The two usual modes of operating for *phimosis* are *circumcision* and *slitting up the prepuce,* with or without removal of the flaps. If a congenital *phimosis* be distended by collection of the urine, it is sufficient to thrust in a lancet at the under and fore part of the prepuce, without injuring the *glans,* and then, after every discharge of urine, to insert a little plug into the aperture for a time.

1654. Circumcision (*Circumcisio,* Lat.; *Beschneidung,* Germ.; *Circoncision,* Fr.) consists in the operator taking hold of the prepuce, above and below, with the thumb and forefinger of the left hand, so that their tips are about a line distant from the *glans;* an assistant draws back the outer fold of the prepuce, as far as possible, to the root of the *penis,* or compresses the *glans* with his thumb and finger; the operator then cuts off that part of the prepuce which he holds, with a stroke of the bistoury, but cautiously, that he do not injure the *glans.* The size of the piece to be removed must depend on the length of the prepuce, and on the extent of its narrowing and thickening; too little, however, must not be removed, as, if so, the inflammation following the operation easily produces fresh narrowing. It is superfluous to hold the part to be cut off with a clamp, as recommended by some practitioners. If, as almost always happens, the outer fold of the prepuce be retracted further than the inner, the latter must also be cut off to correspond. The bleeding, which is often con-

(*b*) Heister; Instit. Chirurg., pl. xxvi. f. 5.

siderable, must be stanched with cold water, with sponge, with continued pressure, or if any single vessel spirt forth, it must be tied.

Samuel Cooper and Wattmann recommend the connexion of the two folds with stitches.

The *Jewish circumcision* differs in that after the child is wrapped from the shoulders to the *pubes* and from the middle of the thighs to the ankles in a cloth properly fastened and laid across the thighs of a sitting man, by whom he is properly held, the circumcisor grasps the prepuce with the thumb and forefinger of his left hand, draws it forwards, and inserts it in the cleft of an instrument similar to a silver spatula. Thus holding the prepuce, and raising the *penis* upright, he cuts off the former close to the plate with a single stroke of a button-ended knife. *The circumcisor now, as quickly as possible, seizes the inner fold of the prepuce with his thumb-nails, which have been specially cut for the purpose, and tears it immediately up to the corona glandis.* He then spirts some water from his mouth upon the wound, takes the *penis* in his mouth, and sucks the blood out of it a few times. A strip of fine linen is then wound round the *corona* and the cut surfaces, as a dressing; and the *penis* laid upon the *pubes*, in a ring to prevent it being touched (1).

Terquem (*a*) speaks in favour of removing the inner layer of the prepuce, and has proposed an instrument like a pair of scissors (*posthetome mobile*) for the purpose.

(1) Many years ago I was present at a Jewish circumcision, and was so much struck with its facility and appropriateness to the purpose, that I have ever since performed the operation in the same manner, except that instead of inserting the prepuce in the cleft spatula, I merely grasp it with a pair of dressing forceps, as close as possible to the *glans*, and then cut it off before them. The tearing up the inner part of the prepuce to the *corona* is a very important part of the operation, and far preferable to its division to that extent with the knife, as, whilst the inflammation is subsiding, the cut edges, especially near the angle of the wound, are prone to adhere together, by quick union; and even if this do not extend far, it causes a girthing of the *glans*, which is inconvenient and often requires a second division to complete the cure. By tearing the inner skin, which should always be torn completely behind the *corona*, or the operation will be useless, the edges of the wound become sloughy, and disposition to quick union is prevented. From repeatedly having performed circumcision in this way, I am sure it is the best mode. And I may add, that, as regards circumcision or slitting up of the prepuce, the former is in every case much to be preferred. I never, however, put in any stitches, as they are not merely superfluous, but add to the necessary inflammation without sufficient reason.—J. F. S.]

Upon the bleedings after circumcision, see Goldmann (*b*).

1655. *Slitting up the prepuce* is performed in various ways, in doing which, however, it must always be remembered that the outer fold should first be well drawn back, so that, as far as possible, an equal division of both folds should be made. Through the orifice of the prepuce is to be introduced Savigny's fistula-knife, or a knife specially for this operation (*c*), with its point guarded, and held flat, till it reach the middle of the *corona glandis;* it must then be turned on edge, and, by sinking the handle and raising the point, it is thrust through the skin, and then being drawn towards the operator, it divides the prepuce at a stroke. The flaps are to be grasped, one after the other, with the thumb and forefinger of the left hand, and cut off obliquely downwards and forwards with the curved scissors, along and close to the *frænum*, or, if they be not too large, they may be left, and gradually shrink and retract. According to Cloquet's mode (*d*), a director should be introduced at the under part of the prepuce, parallel to the *frænum*, and upon it the division made with the knife. If the *frænum* be very short, it must also be divided with the scissors. The longitudinal wound becomes transverse by the retraction of the prepuce, and heals without deformity.

(*a*) Above cited.

(*b*) von Graefe und von Walther's Journal, vol. iv. p. 284, vol. xiii. p. 201.

(*c*) Guillemeau, Benj. Bell, Petit, and Latta, have proposed particular kinds of knives for this operation.

(*d*) Bulletin des Sciences Médicales, 1826, June, p. 206.

Covering the point of a narrow bistoury with wax, for the purpose of introducing it into the aperture of the prepuce, is unnecessary. Many persons in this operation use button-ended scissors; others introduce a director up to the *corona glandis*, and upon it a narrow-pointed bistoury, which they thrust through, after withdrawing the director, and divide the prepuce as just mentioned.

If in consequence of the retraction not having been properly made, the external fold of the prepuce be insufficiently divided, it must be done with the scissors. If the narrowing of the prepuce be of that kind that slitting it up half way is sufficient, this must be done, and the flaps cut off obliquely from above downwards, or left to retract.

In order to prevent the swelling of the flaps of the prepuce, which, by sewing together, causes that of the obtuse angled wound, Fricke (*a*) makes, after the division of both folds of the prepuce as already directed, a cut of the length of half an inch through the skin to the underlying cellular tissue, towards the root of the *penis*. The division of the prepuce at the upper, middle, or under part, is always preferable to that on either side.

Sometimes the narrowing of the prepuce depends on a hard ring, situated in its inner fold; it is then sufficient to pass a narrow button-ended knife behind this ring, and to cut through it in withdrawing the knife.

1656. After the bleeding is stanched, the edges of the wound should be covered with lint, confined with sticking plaster, a small compress, and a narrow bandage, and the *penis* placed upright towards the belly. If inflammation ensue, cold applications are to be made; and in œdematous swelling and gangrene, warm ones. The dressings should be removed as often as necessary.

1657. Although circumcision of the prepuce is by many practitioners considered to have great advantages, especially when its aperture is narrowed merely by a hard ring, if the fore part of the prepuce be not only unnaturally narrow, but also thickened, relaxed, or to some extent contracted into a tube (*b*), yet by this treatment less of the inner than of the outer fold is cut off, and frequently so much less that the object of the operation is not attained, if the inner coat be not also either cut into or cut off; for which reasons the slitting up of the prepuce is, indeed, in general properly employed (*c*), and circumcision only in the simultaneous great degeneration of the prepuce, and then the inner fold must be also specially divided. It is also always most advisable to remove the flaps after slitting, as already mentioned, as they swell considerably after the operation, remain thick and misshapen, and render connexion painful, or prevent it, and only in children after the lapse of some years resume their proper size. This renders Cloquet's proposed operation superfluous.

1658. The operations in which not the whole thickness of the prepuce, but specially only its inner fold, seem preferable to those already mentioned. The origin of congenital *phimosis* is not, as usually supposed, a narrowing of the two folds of the prepuce, but merely a want of extensibility in the inner one. The operation may therefore be most simply performed in the following way. The external skin of the *penis* should be retracted sufficiently far to discover the aperture of the prepuce, into which a narrow-pointed bistoury, with its edge upwards, is to be introduced, or a pair of scissors, and some lines distant of both folds divided. With the fingers of the left hand the skin is much drawn back over the *glans*, which, thus somewhat uncovered, the slightly extensible inner fold appears tightly stretched over the *glans*, and preventing the retraction of the prepuce. This inner fold is now to be divided either with the knife or scissors, as often as is necessary, till the prepuce is quite free upon the *glans*, and capable of being brought backwards and forwards. The bleeding is of no

---

(*a*) Annal. der chirurg. Abth. des Hamburger Krankenhauses, vol. ii. 256.

(*b*) Loder, above cited, p. 86.—Richter, Anfangsgründe, vol vi. p. 191.

(*c*) Zang; Operationen, vol. iii. pp. 34 and 40.

consequence; the whole after treatment consists in repeatedly drawing back the skin over the *glans* and bathing the *penis* in cold water. In a few days the patient is cured without any mutilation. I have frequently performed this operation, with the best result (*a*).

When the cellular tissue connecting the outer with the inner fold of the prepuce, is less extensible, and the outer fold itself less yielding, the latter must be so far cut into as to allow the prepuce being very easily drawn backwards and forwards (*b*).

LANGENBECK (*c*) proceeds in a similar way, though manifestly less simple and satisfactory. After an assistant has forcibly drawn back the general coverings, he grasps the edge of the prepuce with a pair of forceps, introduced within it, and with a pair of scissors makes some little snips at different parts, and so many of them, till the whole prepuce can be completely drawn back. After each snip the prepuce must be still drawn back, till it be everted and the inner fold come into view, in which he then makes the snips which may be still necessary. In old and hard prepuce, with little extensibility of its inner fold, BEGIN (*d*) employs a practice which indeed is to be considered as a modified slitting of the prepuce already described. After previously slitting up the prepuce, he cuts off the corners of the flaps with scissors, so that the wound becomes round; he then retracts the skin of the *penis*, and cuts off the inner fold of the prepuce. as far back as its base, with the scissors. The skin will soon draw together, and healing follows, a V-shaped scar being formed on the inner fold, by which its breadth is increased. According to VIDAL DE CASSIS (*e*), the operator, whilst an assistant fixes the prepuce with a strong pair of forceps, from above downwards, passes through the prepuce, below the forceps, three transverse threads, and a fourth vertically from before backwards; then with strong scissors he cuts off the prepuce in front of the forceps, avoiding the threads. The forceps being then removed, the *glans* is partially exposed with the threads over it. The middle of each thread is now taken hold of with forceps, and being drawn a little forwards, four loops are made, each of which being cut through, eight sutures are formed, which after just sufficiently cutting through the inner fold of the prepuce strongly retracted are tied, and thus the edges of the outer and inner fold of the prepuce brought into contact.

1659. If the prepuce be united to the *glans*, after that it has been cut into where not united, the connexion must be separated with the spatula, the scissors, or the knife; but if their junction be so complete that no instrument can be introduced between the *glans* and the prepuce, a cut is to be made carefully lengthways through the prepuce without injuring the *glans*, and then it must be attempted by lengthening the cut upon the director or by careful dissection, in which the knife is to be always more towards the prepuce than the *glans*, to separate the connexion and remove the divided flaps. In all cases where the union is close and firm, where no instrument can be introduced between the *glans* and prepuce, the operation is excessively painful and difficult, and the result rarely corresponds to the expectation (*f*). In such case therefore the practitioner should be content, if the patient do not urge the more extended operation, to cut into the aperture of the prepuce so far, and so to enlarge it by the introduction of bougies that a free escape of the urine may be effected.

1660. When the connexion of the *glans* with the prepuce by bands is such that many functions of the *penis* are interfered with, the operator holding the *glans* with the thumb and forefinger of the left hand, whilst an assistant draws down and stretches the prepuce near the bands, introduces a narrow curved knife through the bottom of the triangular fold of skin forming the *frænum*, and draws it out. Lint moistened with lead

wash is put between the edges of the wound, and the prepuce kept retracted as much as possible till the cure.

1661. In the treatment of *phimosis* arising from inflammation, its three stages may be observed; *first*, swelling and inflammation of the *glans* which can be got rid of by the proper application of antiphlogistic remedies; *second*, such considerable swelling that the *urethra* is compressed, partial stricture thereby produced, and if unrelieved, abscess, ulcerations of the *urethra*, extravasation of urine, and gangrene of the coverings ensue; *third*, when the chronic *phimosis* cannot be altered or got rid of, the *glans* and the prepuce become firmly connected. In such case the prepuce has often entirely lost its cellular structure, and is thickened; the surface of the *glans* is covered with warts, shrivelled, the proper opening of the *urethra* scarcely to be found, and the *glans* often nearly entirely separated from the spongy body by a deep pit (*a*).

1662. The treatment of *phimosis* caused by simple excoriation or putrefaction of the cheeselike matter, requires frequent injections of warm water with a little *liq. plumbi acet.*, frequently bathing the *penis* in lukewarm milk and water, and placing it against the belly, and also leeches at a distance from the inflamed parts. When the inflammation subsides, slightly astringent injections may be used. If any hard swelling remain about the aperture of the prepuce, it is best to rub in mercurial ointment with camphor, and in œdematous swelling, bags of aromatic herbs, strewed with camphor.

1663. Syphilitic *phimosis*, depending on chancre or clap, first requires corresponding antiphlogistic treatment, blood-letting, leeching, softening poultices, and luke-warm injections, in order to wash out the matter collected between the prepuce and *glans*. As soon as the inflammation and swelling subside, mercury is to be used externally and internally; but if used earlier, there might be transition to gangrene. If with venereal clap and chancre *phimosis* be feared, it can often be prevented by frequent purifying injections, quietude, and laying the *penis* straight upon the belly. If after the inflammation, swelling, and narrowing of the prepuce have ceased, its growing together must be prevented by frequently drawing backwards and forwards.

Under the supposition that contact of the ulcerated surfaces is favourable to keeping up this kind of *phimosis*, and that it always subsides with the cure of the ulcers, many practitioners, putting off the use of mercury and blood-letting, merely introduce beneath the prepuce little rolls of lint smeared with cerate, and after a few days dry lint. This is repeated every twenty-four hours if the secretions of pus be considerable, but only every forty-eight hours if it be trifling. About the fourth day usually, the *glans* can be uncovered, when it may be slightly cauterized with nitrate of silver, and the application of dry lint assists in effecting a cure in from eight to ten days. (Pigné).

1664. Inflammatory and venereal *phimosis* but rarely require operation, and mostly cause bad symptoms, violent pain, considerable bleeding, increased inflammation and gangrene; the danger of general infection is increased, and sometimes growths difficult to get rid of arise about the cut. The operation is only called for when the pus is so retained beneath the prepuce, that it cannot be washed out by injection and bathing, and can only get an outlet by ulceration. In such case, however, it is not necessary to divide the whole prepuce, but it is generally sufficient only to enlarge the aperture of the prepuce so much that the pus can escape and injections be admitted. If the retained matter form a large swelling at

---

(a) Travers, above cited.

one or other part of the prepuce which runs on to bursting through, it must be opened with a lancet for the escape of the pus, and injected. If the prepuce be eaten through, and the *glans* protrude through this hole, it is best to cut off the prepuce on the side next the constricted part, as its opening cannot be again brought to its natural place.

1665. In those cases in which from the pressure of the inflamed and swollen prepuce upon the orifice of the *urethra*, the voidance of the urine is stopped, the ulceration must be prevented by the early introduction of an elastic catheter into the bladder, and if it already exist, at least the bursting of the *urethra*, and extravasation of urine which often causes gangrene of the whole *penis*, be prevented.

1666. The above-mentioned statement (*par* 1658) that congenital *phimosis* does not depend on narrowing of both folds of the prepuce, but merely on deficient extensibility of the inner one, is important in explaining the origin of *Paraphimosis*. If, for instance, the very narrow prepuce be retracted in connexion or in any other manner, its narrow aperture where the two folds meet, is situated like a cord behind the *glans*, the inner coat is turned outwards, and the prepuce everted. The inner coat forms one or more swellings, behind which, and mostly covered by it, the constricted part is exposed. The symptoms caused by *paraphimosis* are various according as the prepuce and *glans* had been previously healthy, or both inflamed, ulcerated, or in any other way diseased. In the first instance they are usually not of importance; the swollen, everted fold of the prepuce inflames and becomes more swollen, and especially on the sides and beneath, the swellings are greatest, become like bladders and transparent. The swelling spreads to the *glans*, but usually in a moderate degree. I have only once noticed priapism accompanying *paraphimosis*. In the second case, the inflammation and swelling are more quick and violent, as both the inner coat and the *glans* may be considerably swelled: retention of urine may occur from the contraction, and even gangrene of the *glans*. In both cases the prepuce may mortify, but usually only the constricted ring behind the *glans* is destroyed by ulceration in consequence of neglect. When the constriction is not very great, and the prepuce is not brought over the *glans*, its folds behind the *glans* may grow together by the accompanying inflammation, and in this way an irremediable deformity be produced.

1667. The *treatment* of *paraphimosis* always requires the replacement of the everted prepuce as quickly as possibly, which must be attempted in various ways. The *glans* should be squeezed with three fingers of one hand for several minutes, or plunged for some time in ice-cold water, to reduce its size, and then with the finger and thumb of the other hand, it must be attempted to draw the prepuce forwards whilst the *glans* is pressed back. This handling however is rarely successful if there be much swelling and some time have elapsed (1). If the *paraphimosis* be accompanied with inflammation, blood-letting, leeching, and other antiphlogistic remedies proportionate to it, must be employed: the handling just proposed will only increase the inflammation. Scarifications of the swollen prepuce, recommended by many, can only be useful by the bleeding. According to Walther (*a*) the swelling of the inner fold should be moderately pressed, so that it may slip in, and the prepuce return

---

(*a*) Ueber die Reduction der Paraphimosis und über die Behandlung der Phimosis; in his Journal für Chirurgie und Augenheilkunde, vol. vii. p. 347.

to its place. By this easy and almost painless handling, **Walther** almost always effects his purpose; compression of the *glans* in doing this is unnecessary, but if this treatment be ineffectual, the operation is required.

[(1) The reduction of *paraphimosis* in this, which is the best way, is often exceedingly difficult, and always excessively painful, so that frequently a strong-minded person will scream like a child from the pain. I have, however, scarcely ever known it fail, and hardly remember it needful to perform any operation with the knife. It requires, however, great patience and perseverance, often for the space of half an hour, at the very least, and I have often succeeded when the prepuce had been everted six or eight days, and it might have been supposed that the adhesive inflammation would have prevented the replacement of the skin. Although the diminution of the bulk of the *glans*, by pressing the blood as completely as possible out of it, is a very important part of the proceeding, yet squeezing out the fluid effused in the prepuce is no less so; and unless both be done, there is great hindrance to the replacement of the skin. I, therefore, always first squeeze gently, but steadily, for a few minutes, the prepuce, till it become somewhat flaccid, and then firmly press the whole *glans* with the thumbs of both hands, whilst the two forefingers of each hand grasp the *penis* behind the everted prepuce, like a collar, and draw it forwards, whilst the thumbs empty and thrust back the *glans*. Or if I do not so suceeed, I grasp the whole *penis* with the left hand, making the thumb and forefinger a collar behind the everted prepuce, which thus rests against it, whilst, with the thumb and fingers of the other hand, the *glans* is emptied, and thrust within the constricted ring, by pushing first one part and then another of the *corona glandis* till it get beneath the constricting band; and this done, the rest soon follows. Immediately that the least bit of the *corona* has been thus got in, that next it must be poked in (no better expression than this can be used) with the finger end, and so on the next, till the greater part has been thus returned, and the reduction is speedily completed. It must, however, be remembered, that directly the return has commenced, the poking must be continued without intermission, as, otherwise, the whole proceeding will have to be repeated, as, on the least cessation, the *glans* again fills and protrudes. If the everted prepuce do not relax by pressure, the constriction being so great that the effused serum cannot be dispersed easily upon the body of the *penis*, it will be found very convenient to make a few punctures through the skin, by which the squeezing presses out the fluid, and then the prepuce is rendered flaccid. It is always advisable to try this mode of proceeding even if part of the prepuce should have become gangrenous, as this is often merely superficial and the replacement puts a stop to its progress. After the reduction, it is well for some hours to wrap the *penis* up in linen, and keep it constantly wet with cold water, for the purpose of preventing the disposition to erection, and re-protrusion of the *glans*, but after that time, a warm poultice will be most agreeable to the patient's feelings, and most favourable to the dispersion of the inflammation. The soreness, however, will commonly continue for many days, proportionate to the severity of the constriction, and its duration. No attempt at retraction of the prepuce, to see what is going on inside, should be made for several days, or the mischief will probably recur.—J. F. S.]

1668. The operation for *paraphimosis* is best conducted in the following manner. A little fold of the outer skin of the *penis*, just behind the constriction, is to be raised and cut through; into this opening a small director, curved at its tip, is to be introduced, and thrust into the cellular tissue beneath the constriction, forwards, till it can be felt on the other side, and then upon it the constricting skin is to be cut through. After this operation the prepuce cannot generally be drawn over the *glans*, because it is too much swollen, and attempts to bring it forward are useless and dangerous; but it returns gradually when the inflammation and hard swelling of the prepuce diminish. If the return of the prepuce be impossible, on account of œdematous swelling, a few little cuts may be made, and its contents squeezed out. The longitudinal cut soon becomes transverse.

In the mode above mentioned, the operation for *paraphimosis* differs, in no respect, from that already described (*par.* 1658) for *phimosis*, namely, the division of the apertr and inner skin of the prepuce. The object of the operation is not the division of the swelling and of the *circular protuberance*, but of the retracted aperture, and of the inner fold of the prepuce. On this presumption, I cannot agree to the unsatisfactory opinion which **Walther** has given of the operation for *paraphimosis* (*a*). **Langenbeck** is also of the same opinion.

1669. If suppuration have already occurred at the circular constriction, the operation is superfluous, for the two folds of the prepuce are already divided, and there is merely the œdematous swelling, which drawing forward the prepuce prevents. In this case, the prepuce must either be brought forward in the way already described, by squeezing and diminishing the size of the swollen inner fold of the prepuce, or several little cuts must be made into it, so as to squeeze out the fluid.

1670. After the operation, merely cold water is to be applied, and the *penis* laid straight upon the belly. If, during the operation, the spongy body be wounded, and there be consequent bleeding, this must be stanched with cold water, or with pressure when it can be employed. An œdematous swelling of the prepuce frequently remains a long while after the operation, to disperse which bags of aromatic herbs, rubbing in mercurial ointment and camphor, and if these be inefficient, cutting into it, or moderate pressure by rolling the *penis*, should be employed.

1671. Constriction of the *penis* may also be caused by threads or thin tapes, and the like, which have been voluntarily put round it. The symptoms, in general, become quickly very severe: the place of constriction is speedily and completely covered by the swelling, and the band will quickly cut into the *urethra*. A thin director must be attempted to be passed beneath the band, which is then to be cut through with a narrow curved bistoury. If the constriction be caused by a metal ring, it must be cut through with a file, or with nippers, and removed in the most careful manner.

Kugler, J., Praktische Abhandlung über die Verengerung der Harnröhre, und ihre Heilung ohne Aetzmittel. Wien., 1843.

1672. *Stricture of the Urethra* (*Strictura Urethræ*, Lat.; *Verengerung der Harnröhre*, Germ.; *Rétrécissement de l'Urètre*, Fr.) results more frequently from a change of the mucous membrane with which it is lined, than in any other outlet. In women only it is very rare, on account of the shortness of the passage.

The narrowings of the *urethra* from other causes, will be treated of subsequently, in considering retention of the urine.

1673. The development of this disease is always exceedingly tedious, and at first is usually not noticed by the patient. He first feels a slight pain in passing his urine, and there is frequently some mucous discharge from the *urethra*, which spots the linen. Gradually more frequent urgency to empty the bladder comes on, and the voidance of the urine is accompanied with much straining. The stream of the flowing water begins to diminish in thickness, is frequently divided and spiral, or if the urine have been already discharged in a stream, a small quantity still falls vertically in drops. Frequently all the urine is not voided at once, and a large quantity is still passed on additional effort. When the proper discharge of the urine is completed, there still remains a small portion behind the strictured part, which, as the *penis* hangs down, gradually escapes by its own gravity. If there be several strictures existing at the same time, the stream of urine is powerless, and the urine drips away. In this state the patient long continues getting alternately better and worse; and after violent exertions, after taking heating food and drink, after connexion, and after catching cold, a momentary stoppage of urine may occur.

[Brodie justly remarks, that "in some cases the urine dribbles away constantly and involuntarily, and the patient's clothes by day, and his bed by night, are absolutely sopped with urine, making him disgusting to himself and to all around him. This involuntary discharge of urine does not indicate an empty and contracted bladder. The bladder, in fact, is loaded with urine, and it is when it does not admit of further distension that the urine overflows, and all beyond a certain quantity escapes, without the patient being able to prevent it, the bladder being at the same time to be felt like an enormous tumour in the lower part of the abdomen." (p. 11.)]

1674. At last the disease reaches its highest pitch; the urine can only be voided with the greatest effort and in extremely small quantity, and its discharge is often completely stopped. By the pressure of the urine against the stricture, the *urethra* behind it is expanded, and it may be so much that the *urethra* tears or is destroyed by sloughing, upon which the urine infiltrates into the neighbouring parts. If only a small quantity of urine be extravasated into the cellular tissue, it forms a hard, definite swelling, which runs on to abscess. In greater extravasation there is a spreading tumour, which may extend from the *perinæum* over the *scrotum*, *penis*, groins, and so on. The skin has at these parts a dusty red, shining appearance; gangrene soon comes on, and, after its separation, fistulous apertures are formed, by which the urine escapes. In this state the constitutional powers often soon sink, and the patient dies.

[" Conceive," says Brodie, " a distended bladder, and the spasmodic action of the abdominal muscles and diaphragm of a powerful man acting like a syringe, and forcing the urine through the lacerated *urethra* into the cellular membrane. In fact, the *scrotum*, the *penis*, the *perinæum*, sometimes even the groins are enormously distended with urine. The first effect of this mischief is to relieve the patient's sufferings. There is no more straining, and the spasm of the stricture, no longer excited by the pressure behind, becomes relaxed, so as to allow some of the urine to flow by the natural channel. After this deceptive interval of ease, another order of symptoms shows itself. The urine, under any circumstances, would irritate the parts unaccustomed to its contact; but, in a case of retention of the urine, it has been long in the bladder, much of its watery parts have been absorbed, and it is in consequence unusually impregnated with saline matter, so that its stimulating properties are much increased. Whereever this acrid fluid penetrates, it first excites inflammation, and then kills the parts with which it is in contact." (p. 13.)

" In cases of stricture, where the disease has existed for many years, and nothing effectual has been done for its relief," Brodie observes, " abscesses form in the cellular membrane external to the bladder, but communicating with it, similar to those connected with the *urethra*. A considerable time elapses before such abscesses present themselves externally, and they point at last in the groin, or above the *pubes*, discharging a putrid, offensive pus in the first instance, and giving exit to urine afterwards. In Dr. Hunter's Museum (now at Glasgow) there is a preparation exhibiting an abscess of this kind communicating with the bladder at the *fundus*, extending upwards in the course of the *urachus*, and opening externally at the navel. I believe that the formation of these abscesses is always preceded by chronic inflammation of the mucous membrane of the bladder, and their existence is marked by severe typhoid symptoms. For the most part they may be regarded as a sign of approaching dissolution." (p. 26.)]

1675. If this do not happen, however, severe symptoms arise from the changes which the mucous membrane of the hinder part of the *urethra* undergoes in severe and long-continued strictures. By the constant irritation of the urine collected behind the stricture, it swells up and becomes spongy; this change spreads upon the mucous membrane of the prostatic part of the *urethra*, the prostate itself enlarges and its mucous follicles swell considerably (1). Hence arises the sensation of weight in the *rectum*, the frequent, often useless straining at stool, the mucous, sometimes purulent discharge which precedes the flow of urine; the fibrous, tenacious urine, with the deposit of long mucous threads upon the bottom of the chamber-pot, which may be drawn out to the extent of two or three feet. The hind part of the *urethra*, and the neck of the bladder at last become so expanded, that the urine is only retained by the stricture, and drips involuntarily (2). By the extension of this diseased change in the mucous membrane to the excretory canals of the *semen*, and the seminal vesicles, there is frequent swelling of the testicles, very quick discharge of the *semen* in connexion, (in which it also escapes without elasticity, and often before the venereal orgasm is finished,) and frequent nightly pollutions. In very severe state of the disease voidance of the *semen* at a half erection, without the patient having any sensation of it, with the efforts to discharge the last drops of urine, and in going to stool, occurs. These changes at last reach the mucous membrane of the bladder, the walls of which then often become considerably thickened; they extend even along the ureters to the *pelves* of the kidneys, which, in like manner, are expanded (3). The great disturbance of the general health which accompanies long-continued stricture now appears; the more or less disturbed digestion, wasting, feverish symptoms at uncertain periods, often accompanied with violent headache and great heat, sometimes with shivering and without particular heat, at other times with cold shivers, great heat, and copious sweating (4).

[(1) The following observations of Brodie, in reference to the combination of stricture, with enlargement of the prostate, are most truthful and well put, and, if borne in mind, will save the patient pain, and the Surgeon credit. "Although the combination of stricture with enlarged prostate is common enough; yet it is not," says he, "so common as it is by some Surgeons supposed to be. An old man, who has a frequent desire to void his urine, and voids it slowly and with difficulty, applies to a Surgeon, whose hand is light and accustomed to the use of the catheter. The instrument is then introduced readily, or, at any rate, meets with no obstruction until it reaches the neck of the bladder, and the case is set down as one of enlarged prostate, which it really is. Another old man, under precisely similar circumstances, applies to a Surgeon, who uses the catheter rudely and incautiously. The *urethra* resents this rough usage; spasm is induced, and the point of the catheter cannot be passed further than the membranous part of the *urethra*. The case is then supposed to be one of stricture, and is treated as such; I need not tell you to how little purpose." (p. 23.)

(2) Brodie mentions a remarkable instance of enlargement of the *urethra* following "stricture at the distance of three inches behind the external *meatus*. The posterior part of the *urethra* was so much dilated, that, whenever he made water, a tumour, as large as a small orange, and offering a distinct fluctuation, presented itself in the *perinæum*: it might be compared to a second bladder. Once, when he sent to me labouring under a complete retention of urine, I punctured the tumour in the *perinæum* with a lancet. Immediately the urine gushed out in a full stream." (p. 8.)

(3) "In some instances," Brodie observes, "the mucous membrane is protruded through some of the interstices of the muscular fibres, forming numerous small cysts, communicating with the cavity of the bladder. These cysts appear to be formed in the following manner; when the patient strains in making water, the mucous membrane, while it is pressed on by the muscular fibres externally, has to sustain an equivalent degree of pressure on its inner surface from the reaction of the urine. Wherever there happens to exist a small interstice between the muscular fibres, the latter force alone operates, and the bulging outwards of the mucous membrane is the necessary consequence. These cysts, however, are not peculiar to cases of stricture of the *urethra*, and they occur equally where the obstruction to the flow of urine arises from an enlargement of the prostate gland, or from any other cause." (p. 25.) He mentions "a case of long-neglected stricture of the *urethra*, in which, on examining the body after death, I found one of the cysts interposed between the bladder and *rectum*; at least, equal in capacity to the bladder itself. * * * For the most part the contents of the cysts are similar to those of the bladder itself; but I shall have occasion to mention a case in which a large cyst of this description contained pure pus, while in the bladder there was nothing but urine." (pp. 25, 6.) He also observes that he has "met with several cases of stricture of the *urethra*, in which the mucous membrane of the bladder was found, after death, not only inflamed, but encrusted, even over a large portion of its surface, with coagulated lymph. Such an effusion of lymph is the result of acute inflammation, differing in its character from the chronic inflammation which produces merely a secretion of the vesical mucus; and it is observed chiefly (if not exclusively) when the patient has died after having been harassed by repeated attacks of retention of urine." (p. 24.)

(4) "Rigors also occur," says Brodie, "in many cases of stricture, independent of abscess. We meet with them most frequently in patients from hot climates. They usually recur at irregular periods, being in many instances brought on by the introduction of a bougie, or the application of caustic to a stricture. The paroxysm very nearly resembles that of an intermittent fever, and it is more severe when it follows the use of a bougie than when it occurs independently of it. In general, the cold fit having been followed by a hot fit, and that by a profuse perspiration, the patient is relieved. At other times, however, the constitution is disturbed for a great length of time afterwards; and sometimes the rigor is followed by an attack of continued fever, which lasts for some

days, or even for some weeks. I met with a case in which a rigor followed the application of caustic to a stricture, and this was followed by an attack of mania, which (if my recollection be correct) did not subside for nearly a month. Another patient had laboured under a stricture of the *urethra* for many years, during which no instrument had ever been made to enter the bladder. I succeeded in introducing a small gum catheter. Having emptied the bladder, I removed the catheter. In a few hours after there was a severe rigor. An attack of fever ensued, attended with rheumatic inflammation of the muscles of the neck, from the effect of which the patient never entirely recovered, though he lived for many years afterwards." (pp. 27, 8.)]

1676. The origin of stricture always depends on, and is accompanied with, a chronic inflammatory state of the mucous membrane of the *urethra*, by which it is swollen up, thickened, and loses its natural extensibility. In many instances the immediate cause of stricture is unknown. It is frequently observed after *gonorrhœa*, especially if that have been long continued, and improperly treated. The causal relations, however, which the stricture has to a previous clap, are often unknown, as it is observed after both severe and slight clap, whether treated with or without injections. Strictures, also, commonly appear long after *gonorrhœa*, often as long as thirty or forty years. Neither their seat nor their extent at all corresponds with that of the previous gonorrhœal inflammation. Scrofulous or gouty inflammation, long-continued onanism, accidents which befal the *urethra*, and long suffering with stone in the bladder, especially in old persons, may be causes of stricture. Warm climates seem to be more favourable to their development than cold. Varicose swellings of the vessels, as well as tumours in the neighbourhood of the *urethra*, may also produce them.

[BRODIE mentions that "in some cases of long standing, we find a gristly indurated mass at the lower portion of the *penis*, where it is covered by the *scrotum*. This is, probably, in some instances, the contracted portion of the *urethra*, thickened and converted into a substance approaching in its character to cartilage. But, in other cases, it depends on a different cause. A gentleman laboured under a stricture, and voided his urine with great difficulty. A hard oblong tumour could be felt in the neighbourhood of the stricture, though somewhat anterior to it, at the upper part of the *scrotum*. I dilated the stricture so as to enable the patient to introduce a bougie for himself; but still the stricture remained unaltered. He died about a year afterwards of an accidental attack of disease in the brain; and I found, on dissection, that the tumour had arisen from a deposition of lymph into the cells of the *corpus spongiosum*. Immediately behind the stricture there was an orifice leading into a long and narrow sinus, extending from the *urethra* into the gristly substance of the tumour. The direction of the sinus was from behind forwards, so that it was evident that it could not have been produced by the improper use of the bougie. I conclude that it was the result of the forcible and the repeated pressure of the urine against the *urethra* behind the stricture." (pp. 8, 9.)]

1677. The most common seat of stricture is at four and a half, or five and a half inches from the orifice of the *urethra*, rarely at other parts (1). The strictured part is, according to the duration of the complaint, more or less hard, white, almost fibrous, generally of slight extent, not exceeding a line's breadth, as if the *urethra* were tied round with a thread; but sometimes it is wider, and then not equally thick, and the canal of the *urethra* is variously curved. These changes seem to result from repeated severe attacks of inflammation, which even affect the spongy body of the *urethra*, and render it thick and hard. Sometimes several distinct strictures exist at the same time. Stricture does not always attack the whole circumference of the *urethra*, it is often valvular, or tape-like, divided and branching, and sometimes runs lengthways. Not unfrequently strictures are noticed, the middle of which is ulcerated. Complete closure of the *urethra* from stricture is very rare; but most commonly in long-continued stricture, the *urethra* in front of it is contracted. The so-called *caruncle*, or growth from the inner membrane of the *urethra*, which was formerly considered the most common cause of stricture, and probably nearly always confused with what we call stricture, is rare. They are frequently found as little masses of soft warts behind the stricture; at other times they are not found behind, but before the stricture; they are commonly similar to those growths observed on the prepuce and *glans*. I have seen in one person, who had frequent claps, the *urethra* filled with round excrescences for an inch behind the *fossa navicularis*.

Hunter (*a*) has described three forms of stricture of the *urethra*; *first*, a permanent stricture depending on a change in the structure of the *urethra*; *second*, a mixed condition of permanent and spasmodic stricture; and, *third*, a simple spasmodic stricture. The adoption of this third kind rests on the notion that the inner membrane of the *urethra* is endowed with actual capability of expansion and contraction, depending on its muscular nature. This opinion is contradicted by examination, which shows that the membranous part of the *urethra* is surrounded with an injectable tissue similar to the spongy body, but in which no muscularity can be discovered (*b*). Charles Bell (*c*), who considered the *urethra* to be simply elastic, supposed that many symptoms of stricture depended on the influence of the perinæal muscles surrounding the neck of the bladder and the *urethra*. Although there may be some grounds for this opinion, a certain capability of contraction and expansion cannot, however, be denied to the *urethra*, as so many excretory passages which equally exhibit no muscular character, and where only very rich vascular ramifications are noticed, are so endowed, without, on that account, distinguishing with the name, *spasmodic stricture* something else than a stricture (depending on a change of structure in the inner membrane of the *urethra*) which is accompanied with great inflammation, great sensibility of surface, or in the neighbourhood of the canal of the *urethra*, and with increased irritability of the surrounding muscles, by which a great degree of stricture may be produced. Here, also, must be distinguished from spasmodic contraction of the *urethra* and neck of the bladder those cases which come on without inflammation and organic change, and merely as a symptom of diseasedly increased sensibility of the bladder and the *urethra*, and mostly only transient (*d*). It must also be remembered, that even spasm may accompany every acute and chronic inflammation. The mistake must not be made of assuming the existence of spasmodic stricture, because on examination of the *urethra* after death no trace of stricture can be found, of which, during life, there were symptoms, and which generally depends on the mode of examination, as, if it be not carefully conducted, nearly everything disappears on cutting into the stricture (*e*).

[(1) "In the majority of instances," observes Brodie, "the disease (stricture) began in the anterior portion of the membranous part of the *urethra* immediately behind the bulb and in the situation of the triangular ligament of the *perinæum*; that in some instances it had its origin in the *urethra*, somewhere between the part just mentioned and the external orifice; and that in a few cases it is confined to the external orifice, and the canal immediately adjoining to it. Occasionally where the original and principal stricture has been in the membranous portion of the *urethra*, there is another stricture anterior to it; and in cases of very long standing it is not unusual to find the greater part of the canal in a thickened and contracted state. (p. 4.) A stricture which affects the external orifice, and anterior extremity of the *urethra*, is, in many cases, connected with an adhesion of the inner surface of the præpuce to the *glans*. Such adhesion is usually the consequence of a congenital narrowness of the præpuce, combined with want of due attention on the part of the nurse to the child's cleanliness; and hence it is that patients who labour under this kind of stricture, frequently declare that they do not know when the disease began, and that they cannot remember the time when the urine flowed in a full stream." (pp. 6, 7.)]

1678. The diseases which may be confused with stricture are, inflammation of the *urethra*, clap, spasm of the muscles surrounding the *urethra*, abscesses or swellings in its neighbourhood, stone, and diseased prostate,

A close inquiry into the course of the disease, a careful examination, and the following circumstances decide the point. In stricture, the discharge after connexion occurs quickly, and recurs usually after a week; a clap rarely appears before the third day, increases, and the pain on making water and inflammation become more severe. Stoppage of the *urethra* by stones is distinguished by the previous symptoms of stone, by the sudden stop to the flow of urine, and the striking of the sound against the stone. Swelling of the prostate is felt by the finger through the *rectum*, the catheter can be readily introduced as far as the prostate, but it then frequently excites severe pain, and most commonly only an elastic catheter can be introduced.

1679. The *prognosis* in stricture of the *urethra* varies according to the seat and condition of the disease. The nearer to the orifice of the *urethra*, the more recent and extensible, the shorter and narrower the stricture is, so much the more easily can it be got rid of. When, however, the symptoms mentioned (*par.* 1675) have set in, the *prognosis* is more doubtful, except that the patient's condition may be rendered tolerable; it cannot, however, be decided whether after the removal of the stricture, these symptoms will diminish or cease. The treatment is in many cases tedious, and relapses are very frequent. If urinary fistula have already formed, what has been already mentioned (*par.* 948) must be borne in mind.

1680. In the cure of stricture, two circumstances must be distinguished, namely, whether the voidance of the urine be completely stopped, or whether the patient suffer under the common symptoms of stricture; the latter only will here be considered, but the former in treating of retention of urine.

1681. The object in the *treatment* of stricture, is to get rid of the obstacle which opposes the passage of the urine, and which is to be effected either by gradual *widening* of the canal of the *urethra*, by the introduction of foreign bodies, as tapers, bougies, or catheters; or *destruction of the stricture* with caustic, with conical catheters or special instruments. If the stricture be in causal relation with *syphilis* or any other dyscrasy, they must be counteracted. General treatment, however, has not in itself any effect on stricture.

1682. The first object of the treatment by *widening* or with *bougies*, is to determine the seat of the stricture. For this purpose, an elastic wax bougie corresponding in thickness with the orifice of the *urethra*, and smeared with oil is to be introduced into the aperture of the *urethra*, the *penis* being held with the finger and thumb of the left hand behind the *glans*, but without pressing the *urethra*. The *penis* is then drawn up, whilst the bougie, held like a writing pen, and gently rolled from side to side, is passed in so as not to get entangled in the mucous membrane. When the bougie has reached the seat of stricture, a mark is to be made on it with the nail close to the mouth of the *urethra*, and thus the distance of the stricture from it is shown.

[“The bougie which is used for the purpose of examining the *urethra* should,” says BRODIE, “be of a full size, that is, large enough to fill the *urethra* without stretching it. A small bougie may deceive in two ways: it may pass through a stricture, and thus lead you to believe that there is no stricture when there really is one, or it may have its point entangled in the orifice of one of the mucous follicles of the *urethra*; or in some accidental irregularity of the canal, and lead you into the opposite mistake of supposing that there is a stricture where none exists. If you use a bougie of the size of the *urethra*, you are not at all liable to the first error, and you are much less liable to the second than you would be otherwise." (pp. 29, 30.)]

1683. A thinner elastic or wax bougie, about the thickness of the stream in which the urine flows is now taken, and a mark made upon it at the same distance from its point as on the former one; after which, being introduced as already directed, an attempt must be made to pass it through the stricture, in doing which all violence must be avoided. The entrance of the bougie beyond the nail-mark shows it has passed the stricture, and this is still further proved when, on drawing it back, it is somewhat held, and if left quite alone it does not rise up. The last circumstance shows that the bougie has bent in the canal of the *urethra* in front of the stricture without penetrating it. If the point of the bougie enter a mucous follicle, it is known by the nearness of the obstacle to the orifice of the *urethra*, by the pain the patient feels, by its further progress when the bougie is drawn a little back, which is effected without the least difficulty, and then again introduced in a different direction, and by the absence of any impression of the stricture which is always observed, when the bougie is withdrawn, to have been made by the stricture. If the bougie will not enter, a smaller one should be tried. If the condition of the stricture be such as to render the passage of the bougie impossible, we must endeavour to obtain an impression of it with DUCAMP's model-bougie, presently to be described, which must be pressed against it a little while for that purpose, so as to give to the point of the bougie to be introduced the proper curve by which perhaps it will pass through the stricture. Or a very thin bougie is to be carried down to the obstacle, and there left some hours, from eight to twelve; afterwards it will of itself enter the stricture and pass into the bladder (DUPUYTREN.) When the bougie have to be pushed beyond the curve of the *urethra*, beneath the arch of the *pubes*, it is most advantageous to give it a proportionate curve, or to introduce a stilette of lead or iron properly curved into the cavity of an elastic bougie. Or if a straight bougie be carried beyond the curve of the *urethra*, as soon as its point gets under the pubic arch, the *penis* must be depressed to lessen the curve of the canal, the bougie gently rotated as it is pushed forwards, and assisted by pressure of the finger in the *perinæum*.

The introduction of the bougie is often rendered difficult by the spasmodic contraction of the muscles surrounding the *urethra*, especially in irritable persons, or if the stricture be in an inflammatory state. In this case the introduction of the bougie may be often effected, if a slight rubbing be made on the *perinæum* with one hand, whilst the instrument is gently pressed forwards with the other, or if it be allowed to lie some time upon the stricture, and then attempts made to pass it farther. Under these circumstances, remedies which lessen the great irritability, as luke-warm bathing, clysters, leeches, and the like should sometimes precede the use of the bougie. No force should ever be employed in passing a bougie; if it will enter only a few lines deep into the stricture, there it should be allowed to remain, and by repeated introductions it will pass further.

Common bougies, *wax bougies*, are prepared in the following manner:—A piece of fine linen, which has been already used, nine inches long and to an inch in width, according to the thickness of the bougie to be made, is to be dipped into melted plaster, and when a little cooled, spread flat and even with a spatula; it is then to be rolled together between the fingers and afterwards between two plates of marble till it is quite firm and smooth. The bougie must be equally thick throughout its whole length to about one inch from its point, from whence it should gradually taper and terminate in a firm round point. Bougies are also made by dipping cotton threads in melted wax till they have acquired sufficient size, after which they are rolled between marble plates. By the addition of various medicaments to the substance of which bougies are formed, were made the *bougies médicamenteuses* formerly in use. The *elastic bougies* are to be preferred, as besides their flexibility they are also tolerably firm, and not so easily dissolved by the urine. If hollow, an iron stilette may be introduced into them, and their strength thereby be much increased.

Wax bougies seem preferable to elastic ones in all cases where there is difficulty in penetrating the stricture, as, on account of their great flexibility, the *urethra* is not easily injured. In very narrow strictures, the introduction of silk-worm gut bougies has been recommended, which enlarge about half their size, and by their softness yield to the directions of the canal. The objection made to them, that by their irregular and hard point, they injure the canal of the *urethra*, and even pierce through it, may be diminished by their proper preparation, and careful introduction (*a*).

If the wax bougie, when it has penetrated the stricture, be a little while withdrawn, an impression upon it from the stricture is observed, by which the condition and extent can be determined. The same also happens with the silk-worm gut bougie.

[In passing wax bougies, Astley Cooper (*b*) directed "always to warm them by the fire, for the purpose of rendering them soft; when, if they are introduced into the *urethra* and pass through the stricture, you will ascertain the distance at which it is situated from the orifice, and the form and size of the stricture will be modelled on the bougie. You then pass another bougie a little longer than the first, and directly that is withdrawn, another still larger. On the following day you again introduce two bougies, that is, if there should be no existing inflammation to prevent it; the first bougie you then use is to be of the same size as the one with which you concluded on the previous day; after this has been withdrawn, you again pass another, a size larger than the first, thus using on every occasion two bougies, always beginning with one of the same size as that with which you had concluded on each preceding time. By adopting this plan, strictures may be cured in a quarter of the time that they usually are, and the strictured part of the *urethra* speedily made to regain its natural size. * * * Never attempt to pass a bougie in its straight state, for if you do, it will be obstructed in its passage, whether there be stricture or not. You invariably give it, before its introduction, the curve of the catheter." (p. 223.)

Abernethy (*c*) says:—"You should pass a bougie very gently, and withdraw it immediately after the first application, and if no reaction ensue, you will find that the part will bear twice as much next time; but if you pass it roughly, the contrary will happen, and you will increase the disorder. You should never repeat the passing a bougie till the effect of the first stimulation is completely gone off. In many cases there is no necessity for introducing them more than once a week."

Brodie justly remarks:—"Success in the cure of this disease will depend on your attending to this important rule. Whether you use a bougie, or a sound, or a catheter, let the instrument be held lightly, and, as it were, loosely in your hand; it will then in some measure find its own way in that direction in which there is the least resistance; whereas, if you grasp it with force, the point can pass only where you direct it, and it is just as likely to take a wrong course as a right one. A stricture will invariably resent rough usage; it will yield to patience and gentle treatment." (p. 68.)

In the treatment of stricture of the *urethra*, there is difference of opinion as to the material of which the bougie or sound should be made, whether wax, elastic gum, catgut, or metal is to be preferred; and whether such instrument should be conical or cylindrical.

Astley Cooper says:—"The bougie I use is made of silver; it is of the form of the catheter, but at the point, and running back for some distance towards the handle, it is conical. The way I use it is this, I first pass down in the manner above described, a wax bougie, for the purpose of ascertaining the form, size, and distance of the stricture. Having obtained a knowledge of these, I then introduce my conical silver bougie, the point of which having entered the stricture, the further it passes the greater is the dilatation produced, in consequence of the form of the instrument. This bougie I have found extremely serviceable, and is the best with which I am acquainted. When it is not at hand I use a common silver catheter instead." (pp. 223, 24.)

Abernethy observes:—"Metallic instruments are good in some cases; if there be a spasmodic stricture at five inches, and another at six, and one beyond it, when a common bougie is passed it may get by the first stricture, but when it reaches the second it

will be so griped by the one through which it first passed, that it will go no further: here, then, the metallic is useful; it cannot be indented, and, being exceedingly polished, it slides on, but it requires great knowledge of the direction of the canal, and great gentleness in passing it."

In the following observations it will be seen that **Brodie** considers difference of situation of the stricture requires corresponding modification in the treatment with instruments.

"Strictures in the anterior part of the *urethra*, but behind the orifice," says he, "require to be mechanically dilated by the introduction of bougies or metallic instruments. At all events, I know of no better method of treatment; and sometimes the patient obtains relief on very easy terms, the dilatation being readily accomplished, and the use of a bougie once in three or four days being sufficient to prevent a recurrence of the contraction. At other times, however, the disposition to contract is so great, that it becomes necessary to introduce the bougie once or twice daily; and, indeed, I have known cases in which the patient was seldom able to expel his urine until the bougie had been employed.

"The simple rules which have been just laid down are not sufficient for the treatment of strictures at the bulb of the *urethra*. The circumstance of these being situated where the curvature of the *urethra* begins, at a distance of six or seven inches from the external orifice, and their liability to spasm, distinguish them from strictures in the anterior part of the canal. The management of them requires greater skill, attention, and experience on the part of the Surgeon; but, at the same time, it must be acknowledged that it leads, on the whole, to more satisfactory results than that of strictures which take place elsewhere. If you were to ask me, how then do you treat strictures at the bulb of the *urethra*? my answer would be, I have no particular method: sometimes I adopt one method, sometimes another, according to the peculiar circumstances of the case. (p. 49.) The methods which are chiefly useful in the case of stricture at the bulb of the *urethra*, are: *First*, The dilatation of it, by means of the common plaster bougie. *Secondly*, The dilatation of it by means of the metallic bougie, catheter, or sound. *Thirdly*, the retention of the gum catheter in the *urethra*, and bladder. *Fourthly*, The application of the bougie armed with nitrate of silver.

"The common plaster bougie, if of small size, should be of a conical shape, but if of a middle size or of a full size, it should be cylindrical. Ascertain the size of the stream of urine, and introduce a bougie of this size, whatever it may be. If the bougie be very small, it may be used straight, otherwise it should be curved like a catheter, but in a less degree. Neither you nor your patient are to be disappointed because the bougie does not enter the stricture at the first trial. In many cases this will not happen until you have seen your patient three or four times; and in very difficult cases, the delay may be still greater than this. When a bougie has once entered the stricture and bladder, allow it to remain for a few minutes. In two or three days introduce either the same bougie or one of the same size. Then withdraw it, and use one of a size larger. Allow this to remain for a few minutes, and after two or three days more, repeat the operation. Thus, by degrees, you dilate the stricture, until it is of the same diameter with the rest of the *urethra*. This method of curing strictures is applicable to a great number of cases; and, whenever it will answer the purpose, I would advise you to resort to it in preference to other methods. The common bougie gives little or no pain; it excites no irritation, unless it be introduced clumsily or rudely; and it can do no harm by penetrating or tearing the membrane of the *urethra*.

"The metallic instruments which I am in the habit of employing are not those which are sold under the name of flexible metallic bougies. These are liable to lose the shape which you have given during their introduction, and, in fact, are at the same time too flexible and too inflexible for any useful purpose. Those which I have, if of a small or middle size, are made of solid silver, the larger ones of silver or steel, or steel plated, or of a composition similar to, but firmer than, that of the flexible metallic bougie. These sounds should be very slightly curved, and for ordinary cases not more than eight inches and a half or nine inches long, exclusive of the handle. You may use them as you would use the common bougie, for the purpose of gradually dilating the stricture, beginning with one of a small size, and gradually proceeding to those which are larger. Sometimes you will find it best to introduce the sound without turning, that is, with the concavity towards the patient's *abdomen*; at other times, you will pass it more readily by keeping the handle, in the first instance, towards the patient's left groin, turning the instrument afterwards as it approaches the stricture. In either case, if you wish to avoid making a false passage, take care that the point is kept *sliding*, as it were, against the upper part of the *urethra*. Press the instrument firmly, but gently, against the stricture, in the expectation that it will gradually become dilated and allow the point to enter; then depress the handle, and pass it into the bladder, provided that you can do so readily, and without the application of force, but not otherwise. Two or three days afterwards, (and the interval ought to be never less than this, and sometimes it ought to be greater,) introduce the sound which has been passed before, withdraw it, and introduce another of a size larger; and thus go on dilating the stricture until that part of the *urethra* has regained its natural diameter. If in the course of these proceedings you are in doubt whether the sound has reached the bladder or not, you may easily determine the point in question by introducing a catheter. You might, indeed, use the catheter from the beginning, but that the openings near the point, and its comparative lightness, render the introduction of it less easy than that of the solid instrument. This method of treatment is applicable to a large proportion of the cases which you will meet with in practice: *first*, to those of old and indurated strictures, which the common bougie is incapable of dilating; *secondly*, to those in which, in consequence of some improper management, a false passage has been formed, into which the point of a common bougie will easily penetrate, but which an inflexible instrument may be made to avoid; *thirdly*, to those in which, from long-continued disease, and without any previous mismanagement, the *urethra* has become distorted and its surface irregular; and, *fourthly*, to several recent cases, in which the smooth, polished surface gives less pain to the *urethra*, and is less likely to induce spasm, than the softer, but less smooth surface of a common bougie. (p. 51–4).

"In treating a stricture of the *urethra* with the gum catheter, you are to introduce it and allow it to remain day and night in the *urethra* and bladder. If the patient can bear it to be retained for a sufficient length of time, the stricture will become dilated not only to the size of the instrument employed, but to a size considerably larger. Perhaps you will be able to introduce the catheter without the wire or stilette. Do so, if possible. If not, you should employ one mounted on a strong, unyielding iron stilette, having a flattened handle, like that of a common sound or staff. Being so mounted, it is more readily directed into the bladder than when mounted in the usual way on a piece of thin flexible wire. When the gum catheter has entered the bladder, withdraw the stilette, and leave the catheter with a wooden peg in its orifice, which the patient is to take out whenever he has occasion to void his urine, it being at the same time secured by a suitable bandage. After three or four days, you may withdraw the catheter for twelve hours; or, if much suppuration be induced in the *urethra*, you may withdraw it for a longer period. Then introduce another catheter, larger than the first; and thus you may, in the course of ten days or a fortnight, dilate a very contracted *urethra* to its full diameter. This is a very certain and expeditious method of curing a stricture. You may by these means sometimes accomplish as much in the course of ten days as you would accomplish in three months by the occasional introduction of the bougie. This method is particularly applicable, *first*, where time is of much value, and it is of great consequence for the patient to obtain a cure as soon as possible; *secondly*, where a stricture is gristly and cartilaginous, and therefore not readily dilated by ordinary methods; *thirdly*, where, from the long continuance of the disease, the *urethra* has become irregular in shape, or where a false passage has been made by previous mismanagement. Under these circumstances, if you can succeed in introducing a gum catheter, and let it remain for a few days in the bladder, you will find your difficulties at an end; the irregularities will disappear, and the false passages will heal; *fourthly*, there is still another class of cases in which this method of treatment is particularly useful. I allude to those in which a severe rigor follows each introduction of the bougie. This disposition to rigor is such, that it is sometimes impossible to proceed with the treatment in the ordinary way. Observe, in these cases, when the rigor takes place. It seldom follows the use of the bougie immediately. It almost always occurs soon after the patient has voided his urine, and seems to arise not as the immediate effect of the operation, but in consequence of the urine flowing through the part which the bougie has dilated. Now, if instead of a bougie you use a gum catheter, and allow it to remain, the urine flowing through the catheter, the contact of it with the *urethra* is prevented, and the rigor is prevented also. I have no right to say that this plan will invariably succeed, but I do not remember that it failed in a single case among many in which I have resorted to it." (p. 57–9.)

Although the harmlessness of plaster bougies is asserted by the high authority just quoted, yet I cannot accord with that statement, for I am quite sure that they are very frequently exceedingly mischievous, and that, even with the greatest caution, much injury may be done by their frequently slipping from the stricture and perforating the wall of the *urethra* in front of it, and producing false passages, and not very uncommonly laying the foundation for urinary abscess and fistula. The quickness with which they often soften by the mere heat of the part is so uncertain, that it is almost impossible to be sure of the precise quantity of pressure which they will bear; and when they once begin to yield, they speedily curl and twist in a very extraordinary manner near their tip, and, though they may not actually penetrate the wall of the *urethra*, yet they may seriously damage it by their increased bulk at this part, as the curve assumes the shape of a corkscrew to a less or greater extent. I have known bougies pushed through the *urethra* again and again, and false passages formed whilst the Surgeon supposed he was making progress in the cure of the stricture, when, in reality he was making matters worse. There are, I apprehend, more false passages made with them than with any other instrument, and few Museums are without examples of such results. I therefore have long since almost entirely given up using bougies, and prefer a catheter or a sound, as with either of these the precise quantity of pressure made, as well as the actual course which the point of the instrument takes, is more readily ascertained, and if it be inclined to go wrong can be more easily and satisfactorily corrected. And with them there is little or no excuse for tearing the *urethra*, In addition to which, experience shows, that the smoother surface of the metallic instrument greatly favours its movement along the *urethra*, and that its tip will often, without difficulty, overcome any little spasm about the stricture, and pass through it, when it is impossible to make a bougie move on without mischief. I do not think it of much consequence whether a catheter or a sound be used; perhaps the former has the advantage of showing at once its entrance into the bladder, by the flow of urine through it, whilst the latter, on the whole, passes more readily, and with less resistance, as its own weight gently urges it on, if it be only kept in the proper direction. A silver sound is preferable to a steel one, as most practitioners who have been in the habit of using it will bear testimony; but it should be solid silver, and not, as is too commonly the case, merely a silver catheter filled with composition, which is not only less weighty than the solid one, but is liable to be broken in two if it be necessary to make any alteration in its curve, as is not unfrequently requisite, to adapt it to the particular case. I think, also, the conical form recommended by ASTLEY COOPER is highly advantageous, and of the best which can be used. A couple of them is amply sufficient for any Surgeon's armamentarium, of which the point of one should be that of No. 3 or 4, and of the other that of No. 5, increasing in size upwards to Nos. 10 and 12 respectively. Some practitioners are in the habit of using a straight sound like a skewer, with a conical point; but if the stricture be in the membranous part of the *urethra*, it is a very dangerous instrument in the hands of most persons, and not adapted, I think, for general use.

The excellent directions given by BRODIE for the introduction of the sound or catheter leave little to be added. The importance of avoiding all violence cannot be too strongly urged. An instrument to be passed into the bladder should rather, as ABERNETHY used to say, be "coaxed," not forced. There are, however, other two points which must be carefully attended to in this operation; the *urethra* may fall into folds, either in its length, or in its transverse diameter, in consequence of which the point of the instrument becomes entangled, and will be at once stopped, and may or may not be thrust through the side of the canal, although at the part where the hitch is, no stricture exists. The *urethra* folds lengthways, when the instrument does not completely fill it, for which reason it is always advantageous to introduce such an one as nearly of the size of the urethra, as will have a chance of its point entering the stricture; and I am convinced that there are few strictures in which it will be necessary to commence operations with one smaller than No. 6 or No. 4; provided the cure only of the stricture is considered, and not the immediate relief of the bladder from retention of urine, in which case a small instrument is admissible. But small catheters or sounds are at all times very dangerous, except in more dexterous hands than those by which they are commonly used; and, as they more quickly slip through the wall of the *urethra* than larger ones, the patient's condition is rendered worse than before, because it often becomes necessary to suspend the use of instruments, if luckily the accident should be discovered, which is far from commonly the case, till the tear has healed up, even if it do not give opportunity for the escape of the urine, and so give rise to abscess. The transverse folding of the *urethra* most commonly occurs in the membranous part, and may happen whether the instrument be small or large, and the obstruction thus produced very frequently leads to the presumption of a stricture when none really exists. This transverse folding depends on the *penis* and *urethra* not being sufficiently drawn forward upon the instrument; so that, when the handle of the instrument is depressed to tilt the point up behind the suspensory ligament into the bladder, the point lifts with it the lax *urethra* in front of it, and, doubling it, forms a valve which blocks its further progress. Attention to keeping the whole length of the *urethra* stretched will generally prevent this, or it may be corrected by elevating the handle of the instrument so that the point disentangles itself, and will then pass on without hindrance. The point of the instrument is also not unfrequently stopped, by depressing the handle too early, that is, before it has completely entered the membranous part of the *urethra*, in which case it strikes against the front of the suspensory ligament, and will not pass further. The greatest care must therefore be taken that the instrument has passed well beyond the ligament before the handle is depressed and the point tilted up; and if then it will not enter the bladder without much difficulty, it is better to pass the finger into the *rectum*, and the end of the instrument being felt, it is in general easily directed into its proper course, and little risk encountered of thrusting it through the *urethra* between the bladder and *pubes*, or between the bladder and *rectum*, which, especially the latter, is of not unfrequent occurrence in not very practised hands. When the instrument has entered the bladder, its point can usually be freely moved in any direction; but when it will not move but forward after its handle is depressed, it is pretty certain it is not in the bladder but in a false passage, and must be withdrawn, and fresh attempts made to carry it in the proper direction, instead of thrusting about and doing serious mischief. The frequency of introducing the instrument must vary according to the irritability of the *urethra*; in some cases it cannot be used more than once a week at first, as it will frequently produce severe irritation in the passage, and be followed by shivering, and occasionally a hot fit afterwards, and it may be necessary to defer the second introduction for even a still longer period. But if no febrile excitement follow, it may be introduced every third or second day, which is generally often enough. It is also very advantageous to bathe the *perinæum* night and morning with warm water, and even immediately after the introduction of the instrument, if it have caused much irritation; and if there be continuing pain, it is best to apply a few leeches. Going into a warm bath twice a week, and the use of leeches to the *perinæum* as frequently, if the stricture be very obstinate, will be often found to assist very materially in hastening the introduction of the instrument, and the widening of the stricture. If the patient be desirous of keeping the passage free, he should persevere in passing a large bougie once a fortnight, long after the cure appears to have been effected, as there is always great tendency to its recontraction. Some Surgeons consider the introduction of a bougie is rendered more easy, by having its tip smeared with extract of *belladonna*. I have tried this plan, but I think not with much advantage. If any benefit be gained from it, it will not be immediate; the bougie thus smeared must be passed down to the stricture, and left in some hours, after which it must be withdrawn, and another introduced. It may, however, be doubted whether the mere residence of the bougie in the *urethra* has not more to do with the relief than the operation of the *belladonna*; for occasionally a bougie thus managed, as recommended by some French Surgeons, will facilitate the introduction of an instrument which previously would not enter the stricture. I do not like cat-gut, nor elastic gum-bougies; they are tough enough to do mischief, but not sufficiently firm to enable us to judge of the pressure made with them, nor to guide them properly.

I cannot say that my experience, as regards the wearing a gum elastic catheter for the cure of stricture, has been so successful as BRODIE has found it. Frequently the irritation set up by it in both *urethra* and bladder has been so great as to compel its removal; and, although I think wearing a silver catheter is more easily borne, if the patient be kept in bed, which, under either mode of treatment, I have always found necessary to enjoin, yet even then I have known in one instance a slough of the *urethra* take place in front of the *scrotum*, without warning, in the course of a few hours; so that, although the case has seemed to be going on well at one visit, on the following day the first step towards a certain aperture in the *urethra* has been made.—J. F. S.]

1684. The time which the bougie should remain in the *urethra* must especially depend on the sensibility of the patient in general, and of the *urethra* in particular. It must be so managed that the patient shall suffer as little pain as possible. The bougie should, therefore, remain only till the patient complains of pain, which on the first day does not exceed a quarter or half an hour, but in an irritable *urethra* not longer than a few minutes. The introduction must be repeated about every other or every day. If the bougie be left in longer, severe pain, swelling of the testicles, febrile symptoms, and abscesses near the *urethra*, often occur. The use of the bougie must then be suspended for a long time, and the inflammatory condition got rid of by blood-letting, quietude, warm bathing, and antiphlogistic diet. Many writers have, however, advised that the bougie should remain for several days, in consequence of which an increased secretion of mucus in the *urethra* is excited, its sensibility blunted, and it is protected against the presence of foreign bodies (*a*). For the most part, patients soon become accustomed to the longer resting of the bougie in the *urethra*, and after some days it may be left. It is then advisable to exchange it for an elastic catheter, which is specially indicated, if there be already fistulous openings, because the patient is thereby relieved from the necessity of its frequent removal, and re-introduction, for the purpose of discharging his urine.

The bougie, or catheter, when left in, should be properly fastened; a tape must be bound tightly round it at the mouth of the *urethra*, the ends of which, carried over the *glans penis*, must be fastened behind it with several turns of sticking plaster, and the loose ends tied together. This mode of fastening is simple, safe, without difficulty, and preferable to fastening a thread to a ring placed upon the *penis*. (DUPUYTREN.)

When the bougie has been long left in, it often, specially at first, acquires an indent from the stricture, in consequence of which, if it be carelessly withdrawn, violent pain may be produced. This may be prevented, if the bougie be frequently moved, and gently drawn up and down.

1685. Thin bougies, or catheters, should be gradually exchanged for thicker ones, which, in not very tough strictures, may be soon; and this should be repeated till the urine is voided in its accustomed stream. The bougie must not be left off at once, but must still be left in for some time every day, or every other day, and afterwards every week for some hours. It will be also advantageous in dispersing the hardness of the membranes of the *urethra* to apply, externally, mercurial ointment, and to give, internally, cherry bay water (*b*) and the like.

If, afterwards, the stream of urine should begin to diminish, and the patient have difficulty in passing it, the use of the bougie must again be prescribed.

In order to effect the expansion of the stricture at pleasure, ARNOTT (*c*) has proposed an instrument, consisting of an oiled silk tube, which, for the purpose of rendering it air-tight, is lined with the thin gut of some small animal, and connected with another tube, through which air can be blown, or water injected by means of a syringe, and retained by a cock. Although the introduction of this instrument is generally as easy as that of a bougie, it is, however, frequently, better, especially in an irritable *urethra*, to introduce it through a canula. When it has penetrated the stricture, it is to be filled with air or water, as long as the patient can bear it without pain.

[Conundrums of this sort are very well pour s'amuser, but every practical person will be very well aware that if a stricture will admit such a contrivance it is sufficiently expanded not to require the assistance of a Surgeon, or any one else, but had better be left alone.—J. F. S.]

1686. The operation of bougies consists in the expansion, compression, and irritation, produced by their introduction and inlying, in consequence of which an increased secretion of mucus, and modification of the vitality and condition of the diseasedly changed mucous membrane is set up. In common cases their presence in the *urethra* excites only a little pain and mucous discharge; but in sensitive persons, violent pain and inflammation, painful erections, transition of the inflammation to the testicles, and swelling of the inguinal glands, will be produced with the inlying of the bougie; also inflammation of the cellular tissue upon the outer surface of the *urethra*,

(*c*) Above cited, p. 92.

terminating in suppuration and extravasation of the urine. All these symptoms require, besides the removal of the bougie, an antiphlogistic treatment corresponding to circumstances, blood-letting, spare diet, luke-warm bathing, and the like. If, during the use of the bougie, an abscess form, with severe pain increased on pressure, DESAULT (*a*) advises the introduction of an elastic catheter, not to open the abscess, but to let it burst of itself, or, if it empty into the *urethra*, to let the pus escape by the catheter; but if it be then necessary, on account of the great size of the abscess, to open it, then always to make a small opening, as a large aperture retards the cure. Although, however, I have in several instances pursued this treatment successfully, yet it appears better, on account of the danger from extravasation of urine, in these cases, as soon as inflammation shows itself, to remove the bougie, and to employ active antiphlogistic treatment by general and local blood-letting, bathing, softening poultices, rubbing in mercurial ointment, and the like, and if fluctuation should show itself, by early opening the abscess (*b*).

[ASTLEY COOPER adverts to the not unfrequent circumstances of bleeding from the *urethra* after the introduction of the bougie; or, it may be added, of a sound or catheter which has been roughly handled, or after the use of a caustic bougie. He says:—"The passing of a bougie is often attended with very considerable hæmorrhage from the *urethra*," and mentions a case in which he "pressed a roller upon the *perinæum*, which instantly checked the flow of blood. A short time after he was sent for to the same patient, the hæmorrhage having returned; he had been lounging before the fire with a foot on each side of the chimney-piece; the warmth coming in contact with the *perinæum*, had brought on a renewal of the hæmorrhage. He made an incision on the part, and divided the artery of the bulb; this operation completely succeeded, and the bleeding was permanently subdued." (p. 225.) I apprehend the necessity for such active treatment is rare, at least I have never seen any need for it, and believe that ABERNETHY's mode of proceeding (*c*) is amply sufficient in most cases. "When hæmorrhage occurs it is best," he says, "to put the *penis* in a tumbler, so that the quantity of blood may be evident. I cover the feet and upper part of the body with the bed-clothes, leaving the *pelvis* bare; I then wash the *perinæum* with vinegar and water. The vessels of the *urethra* speedily contract, and the bleeding stops. I would recommend you to do these things yourself, and not trust to the patient or his attendant."

ASTLEY COOPER also gives the following advice, which, if followed, will often save the patient much suffering:—"Whenever you suspect a tear of the *urethra* in passing a bougie, immediately withdraw the instrument, and desire the patient, if possible, to retain his urine, that it may not irritate the wound, and also to prevent it escaping through the opening and becoming extravasated in the surrounding cellular substance. In this way you give time for a clot of blood to form over the surface of the wound, a slight degree of inflammation is excited, and it becomes healed by the adhesive process without any further mischief." (p. 225.) To this I would add that, under such circumstances, it is advisable that no attempt should be made to introduce the instrument again for several days, and that it should then be done with a very light hand, and with great care.—J. F. S.]

1687. The *destruction of stricture by caustic* is effected either with *nitrate of silver* or *caustic potash*. The application of both these remedies varies, according as the cauterization is made upon the stricture from before backwards, or on its walls in the narrowed part itself.

The destruction of strictures by *ulceration*, in which very hard bougies are violently inserted in the stricture, so that they are grasped by it, in order to produce compression and ulceration of their walls, is to be completely rejected as dangerous and unsafe.

[BRODIE says:—"I am much mistaken if a stricture is not sometimes destroyed, at least in part, by ulceration. For example: I attended a gentleman who had laboured under a stricture of the *urethra* for a great many years. He voided his urine with the greatest difficulty, the stricture being very rigid and unyielding; but I succeeded in introducing a cat-gut bougie, and this enabled him to make water in a small stream. Under

(*b*) DUCAMP, above cited, p. 87.

(*c*) MS. Lectures.

these circumstances he was seized with pain in the act of making water, which lasted for some minutes afterwards, being referred to the situation of the stricture in the posterior part of the *urethra.* The pain became more severe, and the patient described it to be intolerable, saying that he could compare it to nothing but the sensations which he supposed would be produced if melted lead had been poured into the canal. Every half hour he had a desire to make water, and his groans might be heard, not only through the whole house, but even in the street. In the course of a few days these symptoms began gradually to abate, and now it was discovered that the urine flowed in a much larger stream. When the attack had completely subsided, the condition of the patient was much improved, and he made water more easily than he had done for many years." (p. 15.)]

1688. In *cauterizing a stricture from before backwards,* a common bougie is to be first carried down to the stricture, for the purpose of opening the canal of the *urethra,* and the distance from the orifice of the canal must be marked close to it on the bougie. This having been withdrawn, a corresponding mark is to be made on a bougie armed with lunar caustic, which, after having been properly oiled, must be carried down the *urethra* to the stricture, against which it must be moderately pressed, and according to the patient's feelings, for a different length of time, though on the first day not for a minute. In this way the armed bougie is employed every other day, or in obstinate cases, daily. When the slough has been thrown off, an elastic bougie is to be introduced, and thus gradually the natural calibre of the *urethra* is restored.

Bougies armed with lunar caustic are made in the following way:—In forming the common bougie a piece of wire is rolled into it, extending about half an inch into its substance. When the bougie is nearly completed, the wire must be pulled out, and a piece of lunar caustic inserted in its place. The bougie is to be then again rolled, so that the sides of the caustic may be firmly surrounded with the linen, which gives a blunt end to the bougie.

HUNTER (*a*) used, for applying the caustic, a flexible silver catheter, provided with a stilette, which had at its extremity a portcrayon for holding the caustic.

[In the directions which HUNTER gives for the introduction of the caustic, he mentions, it is necessary for the canula to be furnished with a piece of silver or a stilette, having a button at one end, forming a kind of plug, which should project beyond the end of the canula, and give it a rounded end, to facilitate its passage along the *urethra* to the stricture, having reached which the plug is withdrawn, and the portcrayon, which may be attached to the other end of the stilette, introduced in its stead. This apparatus was, however, a very bungling contrivance, and HUNTER doubtless found it so, for HOME mentions in a note, "that before his death Mr. HUNTER left off entirely the use of the silver canula, and used the lunar caustic inserted into the end of a common bougie," (p. 140,) the mode in which it is now, whenever employed. The great advocate for the treatment with lunar caustic was HOME; but it was soon fiercely and efficiently attacked by WHATELY, who shewed the mischievous and dangerous results ensuing from it; for, to use LAWRENCE's words, "if we are to credit the description which HOME gives, nothing would be more safe or effectual than this mode of treatment. When we come, however, to peruse the cases he gives in illustration of the various points of the treatment, we find that serious mischief is sometimes produced by this mode of treating stricture; and as he (HOME) is highly favourable to the plan, we may at all events suppose that he has not exaggerated the ill-effects of the treatment." (p. 802.)]

1689. This mode of cauterization has considerable objection, as especially in strictures behind the curve of the *urethra,* the walls are easily destroyed, false passages made, and considerable bleedings produced. Not unfrequently the aperture of the stricture is closed by the thick slough, and complete obstruction to the voidance of the urine produced: and further, by the hard, formless scar which is produced, the disease again returns more severely than at first.

1690. It is attempted to overcome the greater number of these dis-

---

(*a*) Above cited, p. 139.

advantages by *cauterizing the walls of the stricture.* According to ARNOTT (*a*), after the seat and condition of the stricture have been ascertained by careful examination, and with a very soft bougie, which should be introduced through a canula, and take every impresion of the stricture, a pretty large canula should be carried down to the stricture. A piece of lunar caustic, somewhat smaller than the stricture, should then be pierced through its middle with a metal stilette, and upon which it must be retained, half an inch from the tip, so that the stilette may be surrounded with a piece of common bougie, both in front and behind the caustic. The stilette is then passed through the canula down to the stricture, and through it, so that the caustic can be applied to any part of the stricture. When the caustic has been properly used, a small wad of linen is to be introduced by means of the same stilette and canula, to sop up all the caustic which has become fluid.

[It must not be supposed, as CHELIUS would seem to infer, that Dr. ARNOTT is the original proposer of the treatment of cauterizing the walls of the stricture with lunar caustic; for WHATELY, in his *Observations on Mr. Home's Treatment of Strictures, &c.*, published in 1801, eighteen years before the first edition of ARNOTT's book on *Stricture*, had mentioned among the advantages of his construction of caustic bougies, by gluing the end of the instrument, and applying it to a given quantity of powdered lunar caustic, that "in the first place, the bougie may be of any size, even the smallest size can by this method become the vehicle of this powerful remedy; and *may be readily passed into, or a little beyond, such strictures as are extremely narrow;* or such as are attended with considerable contraction of the orifice of the urethra." (p. 68.) And again:—"If the stricture be open enough to admit a bougie of moderate size, such *a bougie armed with caustic may very readily be passed into or beyond it.*" (p. 72.) Perhaps Dr. ARNOTT was unaware of WHATELY's observations, for it is rather curious, that although HUNTER, HOME, ASTLEY COOPER, LALLEMAND, DUCAMP, and other writers on stricture are mentioned by him, the only notice taken of WHATELY is, that a naval captain had obtained considerable relief under his care; and that after his death the captain's stricture having returned, he placed himself under the care of other Surgeons, but without receiving much benefit from their treatment. He at length, in 1824, consulted Dr. JAMES ARNOTT, who employed the dilator invented by him, from which he obtained considerable relief. (p. 111, *note.*) Dr. ARNOTT's new method is precisely the same as JOHN HUNTER's mode of using the lunar caustic, and which he gave up as inefficient, with the exception that the caustic is held on a piece of wire, by which it is pierced, instead of a portcrayon, as in HUNTER's mode; and with the important addition, that the stilette of the plug, instead of having the portcrayon attached to the other end, as recommended by HUNTER, has "a little dossil of lint fixed on it, which is introduced before the caustic, to absorb any superfluous moisture in the stricture, and after it again, to take up any dissolved caustic which might spread in the canal." (p. 158.) From the above extracts it appears that the proposal of cauterizing the interior of the stricture, whether of much value or little, is WHATELY's and not ARNOTT's; nor the new method other than JOHN HUNTER's old and disbanded one, with the addition of a wipe.—J.F.S.]

1691. If caustic potash be used for cauterizing the walls of the stricture, a bougie of sufficient thickness to enter the stricture with difficulty must be chosen, and passed down to it. A mark is then made on the bougie with the nail, half an inch from the orifice of the *urethra*, and when it has been withdrawn, a little cavity about the twelfth of an inch deep must be made in its rounded end, into which a small piece of caustic, less than the smallest pin's head, must be put, and so pressed in that the edge of the cavity project a little beyond it. To fix the caustic, the bougie must be squeezed together with the fingers, and the interspace filled with lard. Thus armed, and after having been well oiled, the bougie is carried down the *urethra* to the stricture, where it is to be held till the caustic begin to become fluid, and the patient feels a burning pain. It is

---

(*a*) Above cited, p. 157.

then to be introduced a quarter of an inch farther into the stricture, held there about a couple of seconds, and then passed a little further, till by a peculiar feel, or by the approach of the nail-mark to the lips of the *urethra*, it appears that the bougie has penetrated the stricture. If no pain occur, the bougie should be introduced once or twice a day; but if there be pain, it must not be used. The whole operation should not exceed two minutes. Generally after the first use of the caustic there is but little pain, a slight cutting in making water, and its discharge in drops during the first few days. The bougie used should correspond to the diameter of the stricture, the caustic repeated after every eight days, and the bougie increased in size till the natural size of the *urethra* is attained.

[The use of caustic potash in the treatment of stricture, was also first practised by WHATELY (*a*). "It has, however," says he, "been my good fortune to discover a more efficacious, and, at the same time, a less painful and hazardous remedy (than lunar caustic) for the disease in question. This valuable remedy is the *kali purum*, which, if used in the manner, and with the precautions shortly to be described, will be found of singular efficacy in removing the complaint." (p. 23.) The directions for preparing the bougie, and its mode of use, are those above given by CHELIUS. Upon this mode of treatment LAWRENCE observes:—"Mr. WHATELY seems to have been as cautious in the employment of this substance, as Sir EVERARD HOME was bold in his use of lunar caustic, for he recommends you to take a fragment of *potassa fusa*, not larger than the *seventeenth part of a grain*. And he says he never used a portion larger than the twelfth of a grain. * * * I should conceive, according to the description Mr. WHATELY has given of it, that it is just capable of doing that good which the simple introduction of a plain bougie can effect; and I cannot think it had any effect whatever as an escharotic." (p. 802.)]

1692. Although these two modes of cauterizing the interior of the stricture have considerable advantage over that of cauterizing from before backwards, yet they have little certainty in practice, and in many respects are deficient, especially the caustic potash. DUCAMP has the great credit of having proposed a method of cauterization and destruction of stricture, which is distinguished from all the previous modes by its accuracy and certainty.

1693. According to DUCAMP's method, the seat of the stricture is first found with a bougie or sound, and the situation and condition of its aperture ascertained by an exploration-sound, the end of which is covered with modelling wax, which being gently, but steadily pressed against the obstacle, a perfect impress of the stricture is obtained. Its length is also determined by a thin bougie, with a little bulb, and covered with modelling wax, which is fastened to a thicker conductor. For this purpose CHARLES BELL has recommended a thin metallic sound with a button, ARNOTT a thin tube, with a very short leather button, and AMUSSAT (*b*) an explorer. For this object DUCAMP has proposed a peculiar instrument, which, however, does not appear suitable. It is oftentimes necessary, to enlarge somewhat the very narrow opening of the stricture by gradually thicker bougies, which may be left in half an hour.

1694. The cauterization is performed with a caustic-holder, which, being properly oiled, is carried down to the obstacle, and then its inner shaft made to describe a half circle, is protruded into the stricture. For the purpose of cauterizing the whole surface, the instrument is gently turned on its axis. After a minute the inner shaft is to be drawn back into the canula, and the instrument taken out. If the ridge formed by the

---

(*a*) An improved Method, &c., above cited.

(*b*) Above cited, pl. i.

stricture be at the upper or under part, or on either side of the *urethra*, which is shown by the impression on the exploration sound, the caustic must be directed to that spot.

A small piece of lunar caustic is to be put into the inner shaft of the caustic-holder, and the flame of a wax taper directed upon it with a blow-pipe; the caustic soon melts, and completely fills the whole groove. The heat must not be too great, or it will swell up the caustic; it must only be sufficient to fuse it. If any points project, they must be removed with pumice stone. The groove will hold about half a grain of lunar caustic, and, if the instrument be kept in not longer than a minute, about one-third of it will dissolve. As by this method the caustic will be easily too much swollen up, and little remain in the groove, HAHN, according to BERG, proposes the following method:—Some powdered lunar caustic, from six to twenty grains, is to be moistened with water in a little porphyry dish, boiled up over a spirit-lamp, and constantly stirred with a silver knife till the water have evaporated, and the caustic remain fluid in its water of crystallization alone, which may be ascertained by its thin pap-like appearance, and the formation of the crystallization-film. This paste is now to be spread with the spatula on the slightly-heated groove of the shaft, and, when it has cooled, any projection is to be removed with the spatula, or with pumice stone. Whilst boiling, the caustic flies about smartly, and therefore it is necessary to put on a glove, so that the hand be not spotted with black.

1695. If there be only a single stricture, the patient feels, on the day of cauterization, little pain, but without passing his water in a larger stream; on the third day the slough separates, and the stream is then increased. The pain caused by the cauterization is scarcely more than that produced by the introduction of a common bougie. No inflammation occurs; very rarely a discharge, and, if previously existing, it is stopped.

1696. After three days a new impression is to be taken with the exploring sound, which shows how much the opening has increased, and what part still projects, and must be destroyed. A moderate-sized bougie must then be passed and carried into the bladder, to ascertain that there is not another stricture. The caustic is now again to be applied as before, and at the most prominent part. Three days after a third impression is to be taken, and if the parts forming the obstacle project little, and a bougie, No. 6, can be passed with ease, the enlargement of the canal has commenced. If there be still any prominence, or if the bougie pass with difficulty, the caustic must be applied a third time. If there be a second or third stricture, it is to be attacked in one or other of these ways.

1697. For the purpose of keeping the scar as wide as the *urethra* in its natural state, DUCAMP employs peculiar *dilators*, and *bellied bougies* (*bougies à ventre.*) Three days after the last cauterization, a dilator of three lines diameter is introduced, inflated with air, and left in not longer than five minutes. Next day the same dilator is passed, expanded with air or water, and after ten minutes withdrawn and replaced by a bougie of two and a half lines diameter, which is left in for twenty minutes. This bougie is to be introduced for the same time next morning and evening. On the following day a dilator of four lines diameter is to be passed, withdrawn after ten minutes, and replaced by a bougie of three lines, which also, on next morning and evening, is to be left in from fifteen to twenty minutes. Two days after a dilator of four and a half lines is introduced, and afterwards a bougie of four lines morning and evening, each time for a quarter of an hour. After thus proceeding for a week, the bougie is only to be passed once a day, and allowed to remain for a few minutes; for the following four or five, the bougie is to be introduced once daily, and withdrawn immediately. The scar is then well consolidated, and is four lines in width, as in the rest of the urethral canal. DUCAMP (*a*).

DUBOUCHET (*b*) thinks that the bellied bougies, will do as well as the dilators; and, indeed, experience proves it to be so.

1698. DUCAMP cautions against the application of caustic when the *urethra* is inflamed; that in long strictures it is best to destroy them bit by bit, by applying it only for two or three lines, as a longer slough separates with more difficulty, and the canal may be stopped up. If the stricture be six inches distant from the orifice of the *urethra*, a curved caustic-holder should be employed. As DUCAMP's instrument will admit of no twisting, and as, on account of the different dimensions of the *urethra*, the cauterization, even up to six inches, cannot always be performed without danger of making a false passage, so LALLEMAND, AMUSSAT, SEGALAS, and TANCHOU have proposed modified caustic-holders, which may be introduced into the stricture with greater certainty.

For the enlargement of very narrow strictures, LALLEMAND uses catgut. As the use of the exploring bougie, with however great care, in many instances produces great pain, and often much bleeding, and some of the wax may get loose, and by stopping up the canal cause retention of urine, LALLEMAND, if the impression of the stricture be not absolutely necessary, introduces a bougie smeared with wax into the stricture, which, after some time being withdrawn, by the pressure it has suffered, shows the length and even the situation of the obstacle. By the caustic bougie a second and third stricture may be attacked before the first is perfectly removed. DUCAMP says that caustic should not longer be employed after a bougie No. 6 passes easily over the obstacle. LALLEMAND's experience shows that in such cases it is better to cauterize again, than to persist in the enlargement, if changing to a larger sound cause pain. LALLEMAND does not agree with DUCAMP in destroying long strictures bit by bit, but advises cauterizing their whole length at once, as he has never noticed complete retention of urine in such case, nor even in that of deeper strictures from the separation of the sloughs; and, even should it occur, it might be easily relieved by the introduction of a bougie. LALLEMAND considers the subsequent widening of the *urethra* by dilators useless; the bellied bougies will not easily take the necessary bend so as to be carried over the crooked *urethra*, which however I must, from experience, contradict. Elastic curved sounds or bougies are most effective, which should be left in for fifteen or twenty minutes, and should not go beyond the width of Nos. 11 and 12, as if they pass, we may be quite sure of a successful result.

AMUSSAT employs both straight and curved caustic-holders (*c*).

SEGALAS' caustic-holder is distinguished by its introduction, covered, into the stricture. It consists of a graduated gum elastic catheter, in which a canula serves the purpose of sheathing the stilette of the caustic-holder, which, with its olive-shaped button, fits close to the mouth of the canula. The instrument is passed down to the stricture, then the canula carried down it, and, being withdrawn, leaves the caustic-holder uncovered in the stricture.

TANCHOU's caustic-holder, by means of a projecting stilette, is more certainly introduced into the stricture, and the formation of a false passage thereby prevented. It consists of a graduated elastic catheter, with a niche for the reception of the caustic, which is placed on a metal shaft, having its extremity spiral, so that it may be more flexible and more readily applicable to the curves of the *urethra*, and of a silver or gold stilette, which is conveyed through the sheath of the instrument, and also guides it in passing forwards into the stricture (*d*).

1699. Opinion is still very much divided as to the preference of the treatment of stricture by bougies, and their destruction by caustic. It must be borne in mind, however, in making the comparison, that the mischief usually assigned to the destruction of strictures by caustic, has occurred only by the use of armed bougies, (*par.* 1689,) but not since the improved method of DUCAMP; by which it is believed that there is greater

certainty in the application of the caustic, and that the cure is quicker and more constant than by dilatation; that the pain is less as experience proves; that the hardened part which forms the stricture is very little sensitive, and that in the cauterization there is only pain when the sound part of the *urethra* is touched with the caustic. These circumstances are the more weighty, the older and tougher the strictures are, as only in recent cases, and when the stricture is easily extensible, and especially if short, can they be soon cured with the dilator. In strictures which are very close, and also not very long, dilatation may, indeed, be of some service, but the cure is very tedious, and not so radical as by cauterization. The preference given to bougies, because long, and several strictures can be treated together, applies equally well to the improved modes of treatment with caustic. Also in great sensibility of the *urethra*, in which the presence of a bougie can well be borne, and the above-described symptoms (*par.* 1686) are to be dreaded, the sensibility is often much blunted by cauterization. These advantages, however, even in the best modes of applying caustic, are not to be received as general and unconditional; for even with them severe inflammatory symptoms and false passages may be produced, especially if the stricture be seated at the hind part of the *urethra.* The rapidity with which cauterization brings about the cure, is counterbalanced by the transient nature of its result, as the seat of the scar in the *urethra*, after complete subsequent dilatation, has always a decided disposition to contract, by which the most stubborn form of stricture is produced. I have seen in many instances, and even in patients who have been cauterized by DUCAMP himself, relapses, the cure of which was exceedingly difficult. Although the dilatation with the bougies is more tedious than cauterization, yet I must assign to them the greater certainty of a permanent cure. But after the natural width of the *urethra* has been restored the introduction of bougies must be repeated from time to time; and it must be especially noticed that in a stricture, which has been many years forming, and has been of long continuance, the canal of the *urethra* is not in the course of a few weeks to be restored to its natural condition. It is especially not attending to these circumstances, that in dilatation, lays the foundation of relapses. Only in very old hard strictures, in which dilatation cannot be effected, or is very painful and intolerable, do I consider cauterization to be indicated.

Also in fungous degeneration of the mucous membrane of the prostrate gland, which occurs in long-continued strictures (*par.* 1675) when, besides a copious secretion of *mucus*, a sort of fleshy lumps is discharged with the urine, and the urethral canal is not narrowed. LALLEMAND (*a*) has touched every degenerated mucous membrane with his sound in order to decide on its vitality.

[Upon the employment of caustic in the treatment of strictures ASTLEY COOPER says:—"The use of caustic has certainly been very much abused, and in many instances has produced the very worst consequences, and I would say that it never ought to be employed, except where the stricture is accompanied with fistula *in perinæo*, and that fistula behind the stricture; then there can be no apprehension of the caustic occasioning retention of urine, which it has done when injudiciously employed." (p. 224.)

BRODIE observes:—"I very rarely use the armed bougie in my own practice, and I never resort to it in the first instance. My reasons for preferring the other methods of treatment, in ordinary cases, are these:—*first*, although the caustic often relieves the spasm, it also very often induces it. It is true, that in many instances it enables a patient to make water with more facility; but in many instances, also, it brings on a retention of urine; *secondly*, hæmorrhage is a more frequent consequence of the use of the caustic than of the common bougie, and it sometimes takes place to a very

---

(*a*) Above cited, p. 76.

great and to an almost dangerous extent; *thirdly*, where there is a disposition to rigors, the application of the caustic is almost certain to produce them; and frequently the application of the caustic induces rigors where there had been no manifest disposition to them previously; *fourthly*, unless used with caution, the application of caustic may induce inflammation of the parts situated behind the stricture, terminating in the formation of abscess. I have known some cases of abscesses formed under these circumstances, which, from their peculiar situation, have proved more troublesome and more difficult to manage than the original disease." (pp. 61, 2.)

Upon the same point LAWRENCE says:—"From the various results which attend the free employment of caustic in the *urethra*, I think that we may safely say it is a mode of treatment not applicable to bad cases of stricture; that is, cases where the change of structure is considerable, and the contraction is very extensive; and in cases not so serious we know that the application of caustic is not necessary, for the simple bougie, sound or silver catheter, will accomplish the object we have in view. The use of caustic has, in general, been very little favoured on the continent; they have generally healed strictures there without it, and have been averse to it from knowing its ill effects; it has been partially employed in this country, but never got into very great use, and I believe has been generally less and less used, so that at present it is but seldom adopted in the treatment of stricture of the *urethra*." (p. 802.)

With these opinions, as to the disadvantage of using caustic, I fully concur; and I rarely employ it in treating strictures. Another reason may also be given against it, which is, that though for a time, that time only, however, when the slough of the cauterized stricture has been thrown off, and the part is still sore, it may enlarge the passage of the *urethra*, yet as the sore surface heals a new and closer scar is formed, by which the previously narrowed passage will be necessarily rendered still smaller. Every young student knows the common mode of contracting apertures in the soft, and even in the hard palate, by producing sloughs of their margin, with the certain knowledge that the subsequently forming scar will diminish the size of the hole, and that a repetition of the same practice will at last completely obliterate it. And the result must be the same by its application to a stricture, although at first there may be a seeming improvement. I must confess I cannot understand the reason why, although objecting to the use of caustic under other circumstances, ASTLEY COOPER allows it when there is perinæal fistula.—J. F. S.]

1700. *Cutting into the stricture*, and subsequent dilatation, has been also recommended for its more speedy removal; and for this purpose various modes of proceeding have been advised. The older Surgeons used the trocar and the pointed sound (*a*). DOERNER (*b*) recommended a tube through which a stilette, with a lancet point, should be passed, DZONDI (*c*) a catheter open at its end, through which a lancet-shaped knife could be carried forwards and backwards; and in like manner also McGHIE (*d*), AMUSSAT (*e*), DESPINEY (*f*), DIEFFENBACH (*g*), and TANCHOU (*h*). These modes can only be employed with safety in short and not very tight strictures. The proper use of bougies and caustic certainly render it unnecessary, and it can only be considered as indicated when neither dilatation nor repeated cauterization have any result, when the stricture remains hard, and the *urethra* does not acquire its natural calibre.

JAMESON (*i*) seeks for the causes of stricture in an unnatural contraction of the transverse fibres of the *m. accelerator urinæ*, at its fore part, which cross the *urethra* at right angle, as well as of the same part of the *m. levator ani*, in contact with the *urethra*. For the radical cure of this disease, he cuts through the just-named parts, partly through the *penis*, and partly through the *perinæum*.

(*i*) Medical Recorder, 1824, April, p. 251.

Upon breaking through strictures with the conical catheter, refer to Retention of Urine (*par.* 1813.)

1701. In stricture of the *urethra* behind the bulb, especially if a hard, stiff bougie be used, if with it, or with a catheter, force be employed, or if there be abscesses near the *urethra,* its walls may be easily torn, and by the entrance of the catheter or bougie, a *false passage* formed either in the spongy substance of the *urethra* or in the space between the bladder and the *rectum.* This is easily perceived when the instrument is pushed forwards, with much pain, and on its withdrawal, which is done readily, no urine, but only blood flows out. This false passage, in most instances, renders the introduction of a bougie or catheter difficult or impossible, because they always run into it. The careful impress with DUCAMP's exploring sound, and the introduction of a straight bougie or sound, or the application of caustic with LALLEMAND's sound, in the proper direction of the *urethra,* may render the introduction of the catheter possible.

If this cannot be done, and infiltration of urine occur, the following must be the treatment. A sound must be passed into the *urethra* as deep as possible, and a cut made from without towards its point, which will certainly be found behind the stricture. If the false passage be between the *urethra* and the body of the *penis,* the *urethra* will be laid open, the point of the sound having been first bared. A sound is to be introduced into the opened *urethra,* thrust towards the *glans,* and the stricture broken through; or two sounds must be introduced, one by the mouth of the *urethra,* and the other by the wound to the stricture, and pressed together in the proper direction, for which purpose a pointed sound is best; and thus the stricture is penetrated. An elastic catheter is then introduced from the opening of the *urethra* in the wound, and carried into the bladder. If the false passage be between the *urethra* and the external skin, the cut must be made through the latter upon the sound, the *urethra* opened, and an elastic catheter introduced. The treatment of the wound is to be conducted according to the rules already laid down (*par.* 965.)

[I cannot agree with the method, here recommended by CHELIUS, of passing the sound into the bottom of the false passage; for, if this be done, there will be considerable difficulty in finding the *urethra.* The instrument should be carried down *only to the stricture,* and then its point cut upon; which done, the stricture must be cautiously cut through, from before, backwards in the mesial line, by little and little, and the *urethra* behind the stricture continually sought for with a probe's point, the patient being at the same time directed to strain, so as if possible to force out urine, the point of escape of which will afford a guide to the exact track of the *urethra.* Much caution is requisite, that the *urethra* be not completely cleft, and the suspensory ligament deeply cut into, by which the difficulty in discovering the *urethra* is considerably increased. This is an accident to which young and not much practised operators are very liable to fall, and be sorely hampered by. The division of a stricture, and the re-connexion of the two portions of the *urethra* by a catheter, is generally an operation of difficulty under the most favourable circumstances, but when the neighbourhood of the canal has been ploughed up with false passages, the difficulties are considerably increased. It may be well to mention, that the first cut should be made in the *raphe,* and the whole operation continued in the mesial line; and I do not think any material damage is done by cutting through the bulb of the *penis,* which, indeed, is often absolutely necessary, although some practitioners imagine that the generative functions of the organ are thereby interfered with, to which, however, I do not assent.—J. F. S.]

1702. When the *urethra* is closed, as a vice of the first formation, there is either only a superficial membranous closure of its mouth, or the growing together may be deeper situated. In the *former* case, the prepuce is to be drawn back over the *glans,* till the tip of the *glans* is exposed, and then a lancet thrust in, with its edges upwards and downwards, through the closing membrane, and reunion prevented by the insertion of a piece of linen smeared with oil, or of a piece of bougie. In the *latter*, a thin trochar must be pushed in, according to the direction of the mouth of the *urethra*, till it enter the canal, which must be kept open by introducing a piece of bougie; or, if this cannot be done, the *urethra* is to be opened where the collected urine bulges it out. I was obliged to do this in an accidental case of growing together of the urethral orifice, arising from a destroying venereal ulcer, in which there was not the least trace of an aperture in the hardened part to be discovered.

When the *urethra* opens at some distance from the *glans* (*Hypospadias*) it will be necessary for the relief of impotence consequent thereon, to perforate the *glans* with a trocar up to the false orifice, to introduce a canula, and to heal up the lower opening, which must be previously scarified. It is rare that this union can be effected, which, however, does not always frustrate the object of the operation, as the discharge of the *semen* through the new aperture will take place. According to Walther (*a*), the closure of the lower aperture should not be at all cared for. It has also been advised, if this operation do not succeed, to cleave the *glans* from the *urethra* up to its very tip, and to heal the wound over a tube introduced for the purpose, or to cut off obliquely a piece of the *glans* from the false urethral orifice to its tip. The cases, however, are rare in which this degree of misformation becomes the cause of impotence. In one case, a child in whom the *urethra* opened at the root of the *penis*, Dupuytren (*b*) formed, by means of a thin trochar, a new canal, which he cauterized throughout its whole length with the actual cautery; and after the severe inflammatory symptoms had passed by, and the slough had been thrown off, he kept it open with an elastic sound. The fistula closed.

XI.—OF CLOSURE AND NARROWING OF THE VAGINA.

1703. *Closure of the Vagina* (*Atresia Vaginæ*, Lat.: *Verschliessung der Mutterschiede*, Germ.: *Imperforation du Vagin*, Fr.) may be either a vice of the first formation, or may occur subsequently by its growing together. In the *former* case it may depend on union of the *labia* and *nymphæ* throughout their whole extent, in the midst of which commonly a white line is perceived, through the *hymen*, which has no aperture, and is also both firmer and tougher, or by a similar membranous closure more or less high in the *vagina*, or the passage of the *vagina* is closed by a fleshy mass. In the *latter* case, the closure of the *vagina* is the consequence of a growing together which takes place after ulceration and wounds of its walls.

1704. If in congenital closure of the *vagina*, the orifice of the *urethra* be not also closed up, it is rarely discovered before puberty. Then as menstruation comes on there is pain in the back, pressure, straining, weight in the genitals, fullness of the belly, frequent urging to void the urine, sometimes complete retention, difficulty in going to stool, and the like, and no menstrual discharge appears. These inconveniences at first appear monthly, and subside; but at last, when the collection of the blood is considerable, they no longer subside, but increase every month, and general symptoms appear also, anxiety, pale countenance, pain in the belly, faintness, loss of sleep, labour-like pain in the genitals. If the collected blood can find no outlet, it gradually increases in quantity, so that it distends the womb, and empties itself by the Fallopian tubes into the cavity of the belly, or menstruation may be set up in some unusual way. Local

(*a*) Salzb. Med.-Chir. Zeitung, vol. i. p. 188. 1813.

(*b*) Sabatier, Médecine Opératoire, Nouv. Edit. par Sanson et Begin, vol. iv. p. 435.—Dieffenbach; in Hamb. Magaz. der Ausl. Liter., vol. iv. part i.

examination always readily discovers the closure of the *vagina*. When this depends on the *hymen*, or on a mere skin, it is always distended like a sac, by the collected blood, descends and fluctuates.

1705. The narrowing of the *vagina* extends either throughout its whole length, or is confined to one part. In the *former* case it depends on an arrested development of these parts; in the *latter*, is usually the consequence of injury of the *vagina* with loss of substance, in difficult labour, in which a part has been destroyed by gangrene, and the scar contracts the canal, or bands are formed which cross the *vagina*, or partial union of the passage takes place. There are sometimes one or several small holes in the membrane closing the *vagina*, or the *hymen*, although pervious is unusually tough. According to the degree of narrowing various symptoms may be produced, as obstructed menstruation, pain in connexion, and the like. Although the complete introduction of the *penis* into the narrow *vagina* be not possible, yet pregnancy may occur.

1706. The *cure* of the closure of the *vagina* consists in opening it to such extent that it can perform its functions, and in preventing its reunion. This operation is more or less difficult, according as the closure is at the orifice or higher up in the *vagina*, as it is thinner or thicker, or more or less extensive. The prevention of reunion is often attended with considerable difficulty.

1707. In complete closure of the entrance of the *vagina* by the *hymen*, the person must be laid on her back with the thighs drawn up and separated; the *labia* are to be held aside by assistants, and a lancet passed into the middle of the stretched membrane, without injuring the *rectum* or bladder. The aperture is to be enlarged with curved scissors, or with a narrow curved bistoury, introduced upon a director. When the *hymen* is firm and tough, some practitioners advise the removal of the flaps thus formed. If the operation be performed on a child, or in a case where there is not any collection of blood, especial caution is requisite to avoid injuring the bladder or *rectum*. The membrane must then be divided with cautious cuts, and previous introduction of a sound or catheter into the *urethra*, to prevent it being injured. When the *urethra* is also covered with this membrane, the operation must be performed with the greatest care. If the *labia* be completely united, they must be stretched as much as possible to either side, and divided in the middle with careful strokes of the knife, till a director can be introduced, and upon it a bntton-ended bistoury must complete the necessary enlargement. The same proceeding must be adopted if the entrance of the *vagina* be closed by a fleshy mass (*a*).

1708. If the mouth of the *vagina* be only partially closed by the *hymen*, or if the *labia* be united, a director must be introduced through the aperture, usually existing at the upper part near the *urethra*, upon which a narrow button-ended bistoury is passed, and the connexion divided to the necessary extent.

[In infants it is better not to use a knife, but merely to pass a probe through the aperture above down to the bottom of the *os externum*, and then pressing the connecting skin with the probe point upon the finger-nail, till it make its way through, which is generally done with ease; one end of the probe must be held steady whilst the other is drawn forwards, and tears its way out. A piece of lint inserted between the parts is all that is needful. And I do not recollect a case among several on which I have operated, that required any further interference.—J. F. S.]

(*a*) Donauld; in Journal de Médecine, vol xxxvii.

1709. If the closure be more or less deep in the canal of the *vagina*, its condition and extent must first be carefully ascertained by examination by the *vagina* and *rectum*. After emptying the bladder and *rectum*, the oiled finger of the left hand is to be carried up to the closed part, placed upon its middle, and a narrow scalpel, guarded with plaster to within an inch of its tip, or a pharyngotome, or Osiander's hysterotome (*a*) is to be introduced and thrust in the direction of the *vagina*, through the closed part. The aperture is to be enlarged, rather by pressure than by sawing with the knife, according to the situation, where it can be done without danger of wounding the bladder or the *rectum*. The point of the left finger is then to be introduced into the opening, which is to be enlarged with a button-ended bistoury, to the extent and in the direction where it can be done most safely, and seems most necessary.

In complete closure of the *vagina*, without any symptoms of retained menstrual fluid, the operation is contra-indicated, as the womb may be wanting, and the blind extremity of the *vagina* may touch the *peritonæum*. Columbus (*b*), Bousquet (*c*), Meyer (*d*), and Kleinkosck (*e*), have given cases of this kind. Stein (*f*) and Busch (*g*) operated on such cases, and opened the *peritonæum*, in consequence of which the woman died. In a case of Oberteuffer's (*h*), the woman did not indeed die, but the operation was useless. In all these cases the women had not menstruated.

1710. When the canal of the *vagina* is only partially closed, a button-ended bistoury is to be introduced by means of the left fore-finger, or a director, and the connexions divided to the proper extent, without wounding the bladder or *rectum*. Membranous bands are best divided with blunt-ended scissors, which are introduced upon the left forefinger. If closure of the *vagina* accompany pregnancy, the operation must be first performed, when, the pains coming on the membranes present, which can be easily felt through the *vagina* or through the *rectum* (*i*).

[My friend Dr. Locock informs me that he attended a lady who, in consequence of previous difficult labour with tearing of the *perinæum* and *vagina* into the *rectum*, had as she recovered numerous bands formed across the *vagina*. She became again pregnant, and great fear was entertained as to the result of the delivery. He allowed the labour to go on as usual, and as the child's head descended, and the bands became stretched, he divided them carefully with a bistoury, and the case did well. A second pregnancy and delivery followed under similar circumstances. If no operation be performed, and the child's head cannot descend, the womb will burst, and as in the case related by Kennedy (*k*), a triangular flap of the mouth and neck of that organ be thrown down into the *vagina*. In another case, which occurred to Labat, one band had been divided, and whilst waiting for pains to force the other, the whole recto-vaginal *septum* gave way, and the *rectum* and *vagina* became one cavity, leaving, however, the *sphincter ani* unhurt.—J. F. S.]

1711. If the *vagina* be only narrowed, it may be attempted to enlarge it gradually with bougies, sponge tent, relaxing injections, and the like. If pregnancy occur during such narrowing, the *vagina* often yields during that period, and during labour, to such extent, that although previously it had not the width of a quill, yet the expulsion of the child is effected (*l*). In cases where this yielding does not follow, some sufficiently deep cuts

must be made in the narrowed parts (*a*); and, if possible, they should be made on the sides, as if they be directed from before backwards, there is danger on account of the growing together of the *vagina* with the bladder and the *rectum*, of wounding them. If the *vagina* be extremely narrow, opening the head by a cut through the *perinæum* may be required (*b*).

1712. If the menstrual blood be collected behind the closed *vagina*, it escapes after the opening is made, and is black and free from smell. It must be completely emptied by injection, otherwise it will putrify on the admission of the air, and unpleasant symptoms will be produced. At first the most proper injections are those of luke-warm water, of decoction of mallows or marshmallows; but so soon as there is the least smell tincture of myrrh should be added, or injections of bark, with the addition of acid, spirits of camphor, solution of chloride of lime, and the like. If there be active inflammation, smart antiphlogistic treatment must be employed. In order to prevent reunion, it is sufficient, after dividing the *labia*, to keep them separate with a piece of oiled linen. After division at the entrance of the *vagina*, a sufficiently thick plug of lint must be introduced. Where the narrowing was high up in the *vagina*, and tough, its reunion is much to be feared; in such cases it will be necessary to oppose this disposition by the continued introduction of thick plugs of lint, sponge tent, elastic cylinders, and the like. The use of dilators often very considerably assists these means. If it happen that, under these circumstances, symptoms of violent irritation ensue, a corresponding cooling and soothing treatment must be had recourse to.

XII.—OF CLOSURE AND NARROWING OF THE MOUTH OF THE WOMB.

1713. The closure of the mouth of the womb is either a vice of the first formation, or first occurs at a later period, and may depend on a membrane closing the aperture, or on its growing together. The symptoms thereby produced depend on the retention of the menstrual blood, or, if the closure first occur during pregnancy, on the obstruction of the labour.

1714. In the *former* case, closure of the mouth of the womb may be presumed, if, on the appearance of the symptoms accompanying menstruation, no blood flows; if this, again, happen regularly, the womb gradually enlarges, and the belly swells. On examination, the *vagina* is found perfectly free, the distended mouth of the womb descends into the *pelvis*, and may be pushed upwards and backwards by introducing the fingers into the *vagina*. If the mouth of the womb be closed by membrane, it is often found filled out like a sac. The closure of the outer mouth of the womb may be distinguished by the finger, and that of the inner by the careful introduction of a sound.

1715. If the blood collected in the womb cannot escape, it may, as it continues increasing, make its way through the Fallopian tubes into the belly, and cause fatal symptoms. But if the mouth of the womb be closed by membrane, the membrane may be torn by the pressure of the blood which will escape. The only remedy consists in opening the closed part.

1716. When the outer mouth of the womb is closed, the forefinger of the left hand, with its palm or surface upwards, must be introduced up to the part to be opened, upon it a curved trocar, pharyngotome, or OSIANDER's hysterotome is to be passed, and the membrane closing the mouth of the

---

(*a*) PETIT, J. L., Traité des Maladies chirurgicales, vol. vi. p. 110.

(*b*) CHAMPENOIS; in Journal de Médecine, vol. xli.

womb pierced. But if the canal of the neck of the womb, or its inner mouth, be closed, then must the pharyngotome or hysterotome, introduced in the way described, be carefully thrust through the part to be opened, and when the cavity of the womb is penetrated the opening must be enlarged sufficiently with the bistoury.

1717. The discharge of the menstrual fluid must be favoured by injections, as was done in opening the *vagina*, and its reunion prevented by a sufficiently long plug of lint inserted into the new opening, or by the introduction of an elastic tube. The after-treatment must be guided according to appearance of inflammatory and spasmodic symptoms.

The inflammatory symptoms after this operation are so severe that Dupuytren decides upon entirely giving it up, and rather to allow the patient to die more quietly and slowly than to speedily hasten her death by the operation, which always results from inflammation of the womb, and which is the more violent in proportion to the distension of the womb. (Pigné.) Successful cases following this operation have, however, refuted Dupuytren's assertion. Du Cumin (*a*) employed Dupuytren's double lithotome in a case of secondary union of the mouth of the womb, and the result was permanent. The greatest care must be exerted for the complete discharge of all the decomposed blood.

1718. When the mouth of the womb has grown together during pregnancy, or is so changed by hardening and scirrhous degeneration, that it will not dilate during labour, perhaps the whole lower part of the womb may descend so low, that there may be dread of it tearing, then the opening or enlargement of the mouth of the womb must be resolved on (*Hysterotomia vaginalis*, Lat.; *Scheiden-Kaiserschnitt*, Germ.)

1719. In scirrhous degeneration, or hardening of the mouth of the womb, a button-ended concave bistoury must be introduced into it upon the forefinger of the left hand, a cut made into it, and continued from two and a half to three inches into the substance of the womb. The direction of the cut should be to the left, or right, or forwards, or backwards, or in any other way, for the purpose of giving the wound proper size, according to the position of the womb, and, as far as possible, to cut into the part least changed. A cut has also been made in stricture of the mouth of the womb, during labour, throughout its whole length (*b*). The labour proceeds naturally, or may require to be finished by manual and instrumental assistance.

1720. If the mouth of the womb be completely closed, or cannot be felt, a blunt-ended scalpel is to be introduced on the forefinger of the left hand, and division of the protruded mouth of the womb made carefully from before backwards, or from one to the other side. When its cavity is reached, the cut must be made with the button-ended bistoury in the direction laid down, and if the cut cannot be made of sufficient size a second must be made to cross the former. The further treatment is the same as in the former cases.

FOURTH DIVISION.

DISEASES DEPENDING ON THE PRESENCE OF FOREIGN BODIES.

1721. Under the term *foreign* bodies are included not merely *mechanical* bodies conveyed *from without* into our organism, but also those *products which, generated and retained in our organism*, react upon it injuriously.

1722. They may, therefore, be treated of according to the following division :—

I. Foreign Bodies brought into our organism from without,
    1. Into the nostrils.
    2. ——— mouth.
    3. ——— *œsophagus* and intestinal canal.
    4. ——— air tube.

II. Unnatural collections of natural products.
  A. In their natural cavities and receptacles (retentions.)
    1. Ranula.
    2. Retention of urine.
    3. ——— the *fœtus* in the womb or in the belly (Cæsarean operation, division of the *pubes*, Gastrotomy.)
  B. External to their proper cavities and receptacles (extravasations.)
    1. Blood-swellings in newly-born children.
    2. Hæmatocele.
    3. Extravasation of blood in joints.

III. Collections of diseased products.
    1. Lymph swellings.
    2. Dropsy of the mucous bags.
    3. ——— joints.
    4. ——— the chest and *empyema.*
    5. ——— the head and *spina bifida.*
    6. Collections of pus in the breast-bone.
    7. Dropsy of the *pericardium.*
    8. ——— belly.
    9. ——— ovaries.
    10. Hydrocele.

IV. Formations of stony concretions.

Here are reviewed all those diseased conditions which have been already considered, on account of the close relation in which they stand to others; for instance, foreign bodies penetrating from without, and the extravasations in the various cavities, the retention of the bile, of the spittle in the Stenonian duct, and the like.

FIRST SECTION.—OF FOREIGN BODIES INTRODUCED INTO THE BODY FROM WITHOUT.

1723. What relates to foreign bodies, which in various ways complicate wounds, has been already treated of, (*par.* 306 and 338,) both as regards their effect, and the necessity, and the kind and mode of their removal. Here only will be considered those which penetrate into the open cavities of our bodies.

I.—OF FOREIGN BODIES IN THE NOSTRILS.

1724. Foreign bodies which get into the nostrils, are retained, either by the swelling which they undergo, as beans, peas, and the like, which children frequently thrust into their nose; or, if they do not themselves enlarge, are enclosed by the swelling of the mucous membrane of the nostrils, which they set up.

1725. The removal of these foreign bodies is not very difficult if there be not much accompanying swelling; it is often, however, rendered easier by the softness which most of them acquire as they swell up. For their removal, curved, dressing or polypus forceps are used; and if they cannot be got out whole, we endeavour to break them to pieces.

When, in gun-shot wounds of the face, balls remain lodged in the nostrils, they in general so quickly produce violent swelling and inflammation that it is impossible to get them out. In many cases they may remain till discharged by suppuration. But if, by their presence, violent symptoms are produced, they must be removed; and if, on account of the peculiar form and size of the foreign body, the opening of the nostrils offer much obstacle, it may be necessary to slit up one or other of them, and after the removal of the foreign body, to reunite them by the application of a stitch.

The position and size of foreign bodies is often such that they cannot be seized with the forceps; in these cases DUPUYTREN (*a*) advises that they should be pushed backwards, so as to drop into the mouth, which is the way they generally take if left alone for a time to escape of their own accord.

[ASTLEY COOPER used to mention an instance of a ball having been received in the frontal sinuses, which for a time remained quiet, but at last its weight caused ulceration; it descended through the nostrils, and, passing through the floor of the nose into the mouth, caused severe bleeding from the palatine artery.—J. F. S.]

II.—OF FOREIGN BODIES IN THE MOUTH.

1726. Foreign bodies which remain sticking in the inside of the cheeks, in the tongue, or in the palate, may cause severe pain, difficulty in swallowing, and very considerable swelling of the tongue. They can be easily discovered by careful examination, and removed with the forceps. If allowed to remain, they are generally soon got rid of by suppuration.

[I have very recently operated on a case in which a piece of tobacco-pipe, an inch and a half long, had been lodged in the cheek for ten months, without the patient being aware of it. He had fallen with his pipe in hand, and wounded the outside of his cheek; much swelling ensued, and after a few weeks the wound healed, but he could not open his mouth completely nor without pain. Twice during the following twelvemonth the swelling, which still remained, became very painful, increased, and suppurated. The last time he came to me, and the piece of pipe was readily discovered, running from half an inch behind the angle of the mouth horizontally back towards the angle of the jaw, the mouth could not be opened more than half an inch, and each time the jaw was depressed he had great pain at the angle of the jaw. I cut upon the scar, which was very apparent, but had some little difficulty in detaching the end of the pipe, as the scar had probably sunk into its hollow; this done, however, it was easily drawn out with dressing forceps, like a dirk from its scabbard, and was evidently smeared with a mucoid secretion from the sides of the cavity, which it had made for itself. In a few

---

(*a*) Blessures par Armes de guerres; publ. par. MAUX et PAILLARD, vol. ii. p. 232.

days the effects of the operation ceased: he opened his mouth freely, and without pain, and the sinus filled up.

Bodies may sometimes be thrust into the mouth, within the arches of the teeth, and when there become so fixed by the elevating muscles of the lower jaw, as to be incapable of removal without assistance; I knew of a case of this kind in which a girl thus fixed an apple in her mouth, which was only removed by the medical attendant cutting it to pieces.—J. F. S.]

III.—OF FOREIGN BODIES IN THE ŒSOPHAGUS.

1727. Bodies may remain sticking in the *œsophagus* on account of their size or hardness, or their irregular pointed surface. Bodies are often retained in the *œsophagus*, which, as regards their size and character, might without difficulty have passed through it, in which case it would seem that their fixture must be ascribed rather to a spasmodic contraction of that tube. The stoppage is commonly at the upper or lower part, and rarely in the middle of the *œsophagus*.

[I recollect several years since examining the body of a man who was brought to the hospital, and supposed to have died of apoplexy. On accidentally removing the tongue, *pharynx*, and neighbouring parts, an enormous lump of beef was found completely filling up the whole *pharynx*, and compressing the *epiglottis*. Inquiring about the circumstances of his death, it was ascertained that, whilst eating soup for his supper, he suddenly rose from the table, went out of doors, and shortly after was found dead near the threshold. The preparation is in the Museum at St. Thomas's.

I have known an instance occurring twice in the same person, who, had he not been a medical man, would probably have been suffocated before assistance could have been obtained. In eating his breakfast quickly, he suddenly felt choked, could not swallow the morsel in his throat, and could not breathe; he thrust his fingers back to try and pull out the morsel, in which he succeeded, and found the small portion of meat swallowed was attached by a thread of cellular tissue to another portion, which had become entangled in his teeth, and the thread had pressed down the *epiglottis*, so that every effort to swallow made him still worse. The same accident occurred to him a second time, but was in the same way relieved.—J. F. S.]

1728. The symptoms produced under this condition are, local pain, spasmodic contraction of the *œsophagus*, disposition to vomit, choking, or less difficulty in swallowing, symptoms of suffocation, and frequently actual suffocation, which depend partly on compression of the windpipe, partly on the spasmodic contraction of the *glottis*. Sometimes, and, if the body be small and painful, there is merely a local painful sensation. The inflammation may also be so violent, that it may run on to gangrene, though this in general only occurs when forcible efforts are made for the removal of the foreign body.

1729. It is often very difficult to decide upon the presence of a foreign body in the *œsophagus.* When a body more or less bulky, or with an irregular surface, is swallowed, if the patient feel pain at a particular spot, if swallowing be difficult and painful, and the respiration interfered with, yet these symptoms may be merely the consequence of the descent of the foreign body, of wound of the wall of the *œsophagus* at a particular spot, and of the inflammation resulting therefrom. If a bulky body remain sticking in the upper part of the *œsophagus,* it may often be felt externally; or, if the tongue be strongly depressed, its presence may be ascertained either by seeing it, by feeling it with the finger, or with a whalebone or elastic sound, or with DUPUYTREN's (*a*) œsophageal sound of elastic silver, with a little spherical ball at its extremity. These examinations must be always made with exceeding carefulness, and especially may be only made when active inflammation has not yet set in.

[It not unfrequently happens that, after a person has had a fish-bone stick in his *œsophagus,* though he can take food, yet a soreness remains, which is generally supposed to arise merely from the scratching of the lining membrane, and will subside in a few days, it being presumed that, as he swallows solid food, there cannot be anything lodging; and this more especially if an œsophageal bougie have been passed into the stomach. That this opinion may be too hastily formed, is proved by the following example. A friend of mine, whilst eating fish, suddenly felt that he had swallowed a fish-bone, and became so uncomfortable that he was obliged to leave the table, and within a couple of hours went to his medical attendant, who pulled out a piece of fish-bone with forceps. On the following day he still continued very uneasy, his throat being very sore, and felt assured that he had still a piece of bone in his throat; his medical friend, however, very naturally considered the sensation depended merely on the scratch of the bone he had removed. For four days the symptoms of obstruction continued, and he was much harassed, anxious, and became very ill. On the fifth day his son, a very able Surgeon, passed an œsophageal bougie without the least hindrance, and it was then thought quite impossible there could be anything in the passage, and that the symptoms merely depended on the previous irritation. On the evening of the very same day he suffered much pricking in his throat, was attacked with a violent cough, and threw out *another* bone, immediately after which he became easy, and all the symptoms quickly ceased. It is presumed that this second bone had lain obliquely across the *œsophagus,* and that, as the bougie descended, one end of it had been disengaged, as the instrument distended the canal, and, being thus more conveniently and loosely seated, the bone had been shot out by the cough. The remembrance of this interesting case will induce caution in giving a positive opinion of a foreign body not being present in the *œsophagus,* although swallowing may be effected, and even a bougie passed without obstruction. —J. F. S.

In the College Museum there is the whalebone handle of a punch-ladle, marked "It had been in the *œsophagus* sixty-eight hours without doing mischief;" but nothing more is known about it. It was in HEAVISIDE's collection.

MONRO indeed mentions the case of a boy who had attempted to swallow a halfpenny: it remained in his *œsophagus* "three years, and possibly it might have remained there for a much longer period had he not been seized with consumption, which proved fatal to him. Upon examination the gullet was found closely embracing the halfpenny, and considerably expanded by it. A halfpenny stuck in the gullet of another boy for six months, and was afterwards extracted by MONRO's father with a blunt hook." (p. 18.) He also mentions an instance in which an extraneous body, detained at the origin of the gullet, became lodged in a sac of some length, which descended behind the *œsophagus.* (*ib.*)]

1730. Foreign bodies in the *œsophagus* may either be drawn upwards, or thrust down into the stomach, or removed by a cut into the *œsophagus.*

1731. The *removal* of the body *upwards* may be effected by vomiting, produced either by irritating the throat, or by the exhibition of an emetic,

---

(*a*) SABATIER, Médecine Opératoire, vol. iv. p. 52.

if swallowing be not entirely prevented, or by the injection of a solution of tartarized antimony into a vein (*a*). It must, however, be observed, in reference to the vomiting, that if the body firmly close the œsophageal tube, and will not be moved by the sickness, the mischief is increased, and even tearing of the *œsophagus* may ensue.

If the foreign body be at the upper part of the *œsophagus*, it may often, if the tongue be strongly depressed, be seized with the finger, or with a pair of œsophageal forceps, and withdrawn. If it be lower down, it may be removed also by the forceps, or a blunt hook, formed of a piece of wire bent together; or by a whalebone sound with a piece of sponge attached to its extremity, which is to be passed below the body, and when the sponge has swollen by the absorption of the moisture, may be withdrawn. Little pointed bodies, as needles, fish-bones, and pieces of bone, are generally more easily removed with the sponge. A flexible sound, having its extremity armed with several loops of metal, has been recommended for this purpose. Bulky bodies, which completely fill the *œsophagus*, are very difficult of removal, because the instrument cannot be passed beyond them. Attempts at removal must always be made with great care and consideration. **Delpech** (*b*) objects to the use of the hooks and metallic loops as inefficient and dangerous.

The peculiar operation of the vomiting is not merely the commotion but the inverted contraction of the muscular fibres of the *œsophagus*. For the purpose of making the *œsophagus* slippery, mucilaginous and oily remedies, melted butter, oil with camomile tea, or yolk of egg and the like must be administered. Tobacco clysters are often advantageous in producing vomiting and diminishing the spasm. The removal of a fish-hook, which had been swallowed, the line of which remained hanging out of the mouth, by means of a perforated bullet through which the thread was passed, and the bullet allowed to drop down into the curve of the hook so as to shield its point, is mentioned by **Bright** (*c*).

1732. In *thrusting down foreign bodies into the stomach*, a whalebone sound, with a piece of sponge at one end, commonly called a probang, first smeared with oil, is employed. This mode is to be practised especially if the foreign body be soft and have a smooth surface; but if it be rough or pointed, considerable injury to the *œsophagus* may be effected by thrusting it down, and it may be even of such character, that on account of its mere presence in the *œsophagus*, dangerous symptoms may be dreaded. Under these circumstances, only the most urgent symptoms, and the impossibility of getting rid of the body in any other way, will determine that it should be thrust down. The patient may be allowed to swallow mouthfuls of chewed bread, and the like, which often drive the body down, and a blow between the shoulders will often loosen it.

If a body capable of being broken up, as for instance, a potato remain sticking in the upper part of the *œsophagus* and cannot be thrust down into the stomach, attempts must be made to press it upwards, with the fingers upon the surface of the throat, as **Dupuytren** did very successfully, and quickly relieved the patient after all other efforts had been in vain. (**Pigné**.)

[Before proceeding to thrust an extraneous body down the *œsophagus*, a careful examination should be made with the finger, to ascertain if it be within reach, and can be removed; the importance of doing this is proved by the following case, which **Astley Cooper** was accustomed to relate (*d*). A child, whilst dining with his parents on his birthday, swallowed a fish-bone, and was attacked with violent cough; **Cooper**, not being in the way, another Surgeon was found, who passed a probang; the symptoms,

(*d*) MS. Lectures.

however, became worse, were followed by convulsions, and, between ten and eleven o'clock of the same evening, the child died. Having obtained permission, COOPER opened the *larynx* with a lancet, and found a piece of fish-bone situated just at the *glottis*, which he readily hooked out with his finger-nail.

Dr. BROWN (*a*) mentions the case of a woman who, in eating oatmeal porridge, swallowed a piece of a broken delf plate, which pierced the *œsophagus* on the right side, midway between the cricoid cartilage and the breast-bone. She soon made an effort to vomit, and a discharge of blood from the mouth ensued and repeated on the passage of a probang, which she thought displaced the bit of delf. On the day following she was seen by BROWN, and had then inflammation and swelling of the external *fauces* in the line of the *œsophagus*, with total inability to swallow. The foreign body could not be felt externally; and a probang was twice passed with facility. Leeches and cold lotion were applied, and on the sixth day the inflammation had almost ceased, and she swallowed well. On the ninth day she was attacked with pain in the stomach, which lasted two days, and on the tenth she vomited a pint of dark fœtid blood, which continued in smaller quantities. On the twelfth day she spat up more than a pint of brown fœtid sputa, and died at midnight. No examination was permitted. BROWN considers that the bit of plate was at first thrust down into the stomach, and that the inflammation of the *œsophagus* depended on the violence with which this was done. He imagines that the fatal symptoms resulted from the hard substance wounding the stomach, especially as that organ was comparatively empty from the accident to her death. And that the pain in the left *hypochondrium* pointed out injury to the left extremity of the stomach, near the *cardia*, where some large branch of the coronary, or left gastro-epiploic artery must have been divided, as the quantity of blood poured out was so large as to colour the fæcal discharges.

[My friend and pupil TUÑALEY, of Camden Town, has given me the following case, which shows the propriety of ASTLEY COOPER's advice, and which, but for the prompt and judicious treatment, would also probably have terminated fatally, although the foreign body was merely a piece of bristle from a brush, about an inch in length. A lady, whilst eating bread and butter, felt something in her mouth which seemed like a piece of wood, and not choosing to spit it out, as she was in a party, determined to swallow it with the morsel in her mouth. In doing this, the sharp substance lodged in her throat, produced a constant pricking, and in the course of a few hours cough and repeated attempts at deglutition. She was seen shortly after by a medical man, who examined the throat, and, finding nothing, considered it merely a case of local irritation, and treated it accordingly. Next day she was worse, and an emetic was given, which quickly aggravated the symptoms to such an extent, as to threaten immediate suffocation. Twenty-four hours after the accident, TUNALEY saw her, and it was then necessary at once to perform tracheotomy, which he did immediately below the cricoid cartilage; and, scooping out its under edge, he introduced an elastic catheter, which relieved her directly. Four hours after, when the spasm had subsided, he made an examination with his finger, by the mouth, and could just feel, when an attempt to swallow was made, the point of what he took for a pin; but it was not under command of the finger. He then passed a pair of dressing forceps, bent for the purpose, into the throat, and, after persevering efforts, as the patient's exhaustion would admit, during two hours, at last succeeded in pulling out a bristle, which, he considers, had penetrated the mucous membrane at the root of the *epiglottis*, and, by its continued irritation, had produced the spasm of the *glottis*. The patient speedily recovered.—J. F. S.]

1733. When the body has caused severe inflammation and diseased contraction of the *œsophagus*, all attempts at its removal must be given up, and the treatment confined simply to blood-letting, leeching, oily injections, and if there be accompanying spasm, opium. When by these means the inflammation, swelling and contraction of the *œsophagus* have diminished, it not unfrequently happens that the body gets loose, and can be removed one way or another.

1734. Whether the body be drawn up or thrust down, frequently local inconveniences remain in the *œsophagus*, as wounds, inflammation, and suppuration, which require corresponding antiphlogistic and soothing treatment. Narrowing of the *œsophagus* may result at a subsequent period, and if the body be bulky, suppuration even may ensue.

(*a*) Edinburgh Med. and Surg. Journal, vol. xxxvi. p. 56. 1831.

1735. Thin and pointed bodies, needles for example, may penetrate the walls of the *œsophagus* and gradually make their way through the neighbouring parts, so that they often reappear at very distant parts. This more frequently occurs when the bodies have passed into the stomach, and then travel through the different organs, sometimes accompanied with no pain, but at other times with great pain.

1736. When the foreign body can neither be pulled up nor thrust down into the stomach, if it produce urgent symptoms, and be not very low in the *œsophagus*, or if it be of such kind that its descent into the stomach would be productive of great danger, then it must be removed by cutting into the *œsophagus* (*Œsophogotomia.*) This operation is always one of the most difficult and dangerous, though under the circumstances it must be held to be the only means of relief, and by observing certain rules, is much facilitated. The parts of which injury is to be feared are the carotid artery, the internal jugular vein, the recurrent nerve, and the thyroideal arteries.

CALLISEN (*a*), as well as BENJAMIN BELL and RICHERAND, only allow œsophagotomy when the foreign body can be felt externally, and in the contrary case will have an opening made in the windpipe to prevent the danger of suffocation. According to ZANG (*b*), however, the operation may be undertaken, if nothing be felt externally, if only the place be known where the body is situated. In these cases also the mode of operation laid down by VACCA BERLINGHIERI may be safely performed.

[As the more serious symptoms which occur when a foreign body sticks in the *pharynx* or *œsophagus*, depend on the pressure it makes upon that part of the air-tube to which it is opposite, I think it would be advisable to perform tracheotomy in preference to the difficult and dangerous operation of cutting into the *œsophagus*. This mode of treatment has been successful, as in the case of the boy who attempted to swallow nine pistoles wrapped in a piece of cloth, mentioned by HABICOT (*c*). The packet stuck in the narrow part of the *pharynx*, and he was almost suffocated. Attempts to thrust it down were made; but in vain. HABICOT, therefore, to relieve the most urgent symptoms, cut into the windpipe; the difficulty of breathing, the swelling and blueness of the face ceased immediately; and the money then thrust down with a leaden sound into the stomach, was passed by stool a few days after.]

1737. According to VERDUC-GUATTANI, the operation is to be performed in the following manner. The patient having been placed in an arm-chair, or laid upon a table, and his head properly held by an assistant, a cut from two and a half to three inches in length must be made vertically through the skin and cellular tissue, upon the left side of the air-tube between the *larynx* and the collar-bone. Then, the assistant having drawn the edges of the wound asunder with blunt hooks, and the blood being absorbed with a moist sponge, it must be endeavoured to dig under the edge of the thyroid gland with the handle of the scalpel, and keeping still on the one side of the air-tube, and using the blade of the knife as little as possible, the *œsophagus* is to be laid bare, and so cut into that the foreign body may be removed with a pair of straight forceps, without tearing the edges of the wound. If the foreign body be a little distant from the opening, a pair of curved forceps must be used for its removal. Any spirting vessels must be immediately taken up during the operation, as well also the thyroideal arteries, if they come in the way, before cutting them through.

ECKOLDT's method, in which a cut is made through the skin, close to the middle of the *m. sterno-mastoideus*, and the division of the cellular tissue in the triangular space formed by the division of this muscle before its insertion into the breast- and collar-bone, and the *œsophagus* laid bare and cut into, is manifestly less safe than that just described.

(*a*) Systema Chirurgiæ, vol. ii. p. 421. (*b*) Operationen, vol. iii. p. 40.
(*c*) Mém. de l'Acad. de Chir., vol. xii. p. 243. Edit. in 12mo.

1738. In those cases in which the foreign body forms no perceptible swelling externally, and for the purpose of especially projecting the wall of the *œsophagus*, it has been recommended to introduce a silver catheter, or a forked curved sound, through the mouth into the *œsophagus*, and to raise its left wall into the wound. The arrow-sound has also been advised for this purpose. RICHERAND (*a*) objects to the introduction of any instrument into the *œsophagus*, as a guide. VACCA BERLINGHIERI (*b*) has, however, proposed an instrument by which œsophagotomy is more easy and effectual than by any other mode.

1739. The patient is placed on a low stool; the head held firmly against the chest of one assistant, and the rest of the body by another. The skin-cut is to be made on the left side of the neck, in the direction of the thyroid and cricoid cartilage, on a fold of skin from the upper edge of the thyroid cartilage to two inches below it; if the *m. platysma myoides* be not then cut through, it must be divided with a second stroke of the knife into the underlying cellular tissue. The *ectropœsophag*, with the spring thrust fully forwards and thus completely closed, is to be introduced so deeply into the *œsophagus*, and so directed that its lower end corresponds to the lower angle of the wound. The fore and middle fingers are now to be introduced into the side rings of the canula, and the thumb into that of the shaft, which being drawn back, its spring end is set free, and with its olive-shaped knob, the wall of the *œsophagus* is thrust into the wound. The instrument is now held steadily by an assistant, the cellular tissue carefully cut into, and the *œsophagus* laid bare by drawing the *m. sterno-mastoideus* backwards, the *m. sterno-hyoideus* and *sterno-thyroideus* forwards, (with the assistance of the finger or a blunt hook,) and then the *m. omo-hyoideus*, which crosses the wound obliquely, is divided on a director. The *œsophagus* now appears to more than the extent of an inch, and must be cut into on the side, and a little forwards, between the canula and the diverging arms of the shaft, for two lines above the olive-shaped knob of the latter, and the cut enlarged upwards as far as may seem necessary. A blunt hook is then introduced into the *œsophagus*, to keep it steady. The ectropœsophag is now taken out, and the foreign body removed with the finger or forceps.

The ectropœsophag may be so easily arranged, that it may be used even if the operation be performed on the right side.

1740. According to BEGIN (*c*), it is impossible to operate upon the *œsophagus* in the region prescribed by VERDUC-GUATTANI'S plan, or properly to introduce the instruments recommended for introduction by others, and to retain them in suitable position, as the irritated parts cannot bear constant touching, and the breathing has already become difficult. His method, which is founded on the most careful consideration of the anatomy of the parts concerned, and which has been several times performed on living persons, is the following:—The patient is laid upon a narrow bed, his shoulders and chest slightly raised, the head a little bent back, and supported with a pillow, and the neck moderately stretched. The operator standing on the left side, makes a cut through the skin, along the groove between the sterno-mastoid muscle and the windpipe, which he begins a finger's breadth above the sterno-clavicular articulation, and

(*b*) Journal VON GRAEFE und VON WALTHER, vol. v. p. 712.—Chirurg. Kupfertaf., pl. cxxxv.

(*c*) Dict. de Méd. et de Chirurg. pratique, vol. xii. p. 152; and Nouv. Elém. de Chirurgie et de Méd. Opérat., vol. i. p. 260. Second Edition.

carries up as high as the upper edge of the thyroid cartilage. He now divides with long strokes the *m. platysma-myoides* and cellular tissue, and descends deeply into the cellular space between the windpipe and *œsophagus* within, and the deep vessels and nerves without, which are covered by the sterno-mastoid muscle, and the assistant, standing on the patient's right side, draws inwards the parts on the inside of the wound with his fingers or with a blunt hook, and the operator, with the fingers of his left hand thrust in more deeply draws outwards the parts on the outside of the wound, and with the point of his finger covers the vessels and nerves. The *m. omo-hyoideus* is then seen running obliquely outwards and downwards in the upper half of the wound, which, a director having been introduced beneath, must be divided. The *œsophagus* now appears, and is known by its position behind the windpipe and *larynx*, its round fleshy surface, its movements and hardness in the attempts to swallow. If the foreign body form a projection, it must be immediately cut upon; but under contrary circumstances, the knife is to be carried boldly in the middle of the wound parallel to the axis of the *œsophagus*, into it, and an opening made about half an inch long, from which immediately some mucus and spittle flow out, and in which, by the contraction of the circular fibres, the mucous membrane becomes visible. A button-ended bistoury is now introduced upon the forefinger, and the wound enlarged sufficiently upwards and downwards to admit the introduction of the forceps. It is better to enlarge the wound upwards rather than downwards, as wounding the superior is less dangerous than wounding the inferior thyroideal artery. Every bleeding vessel must be immediately taken up during the operation.

1741. No precise rules are laid down for the removal of the foreign body; it must depend on the delicacy of the touch, manual dexterity, and thought of the operator upon the moment, to determine how the difficulties may be best overcome. Curved and pretty strong polypus-forceps, with double curves, are in general most convenient, and a sufficient number of them, of various form and size, must be in readiness. (Begin.)

1742. After the removal of the foreign body, quick union should be aimed at according to the usual mode, with dressings; the edges of the wound are to be brought close together with sticking plaster, and the head kept inclined a little backwards and to the right side. For the first eight days the patient must be supported only with nourishing clysters and baths; and then with gelatinous substances in small quantities by the mouth; at first the patient's tormenting thirst must be quenched with Seville orange strewed with sugar, (*par.* 473,) and taken into the mouth. But, according to Begin, should the wound unite neither by sticking plaster, and still less by suture, as in the condition of the walls of the *œsophagus*, from the more or less severe inflammation and so on, agglutination, as in ordinary wounds, is not to be expected, but the edges should only be brought together, covered with perforated cloths spread with cerate, and wadding with compresses, fastened with a circular bandage. As the patient subjected to œsophagotomy becomes wasted by his incapability to swallow, want of rest and so on, some nourishing broth should be conveyed into his stomach by means of an œsophageal tube, the day after the operation.

IV.—OF FOREIGN BODIES IN THE STOMACH AND INTESTINAL CANAL.

Hevin, above cited, p. 590.

1743. When bodies, insoluble by the powers of the digestive organs, are thrust down or swallowed into the stomach, they may produce different symptoms, depending principally on their form and nature. Bulky bodies often pass without any difficulty through the whole intestinal canal; pointed bodies are easily retained, and produce frequently inflammation and ulceration.

[Of the foreign substances received into the stomach, the most remarkable account is that given by Dr. **Marcet** (*a*), of the sailor who swallowed a number of clasp knives. In June, 1799, after having witnessed a display of jugglers' knife-swallowing, he, in a drunken fit, boasted he could do the same, and accordingly swallowed four pocket-knives successively. On the following afternoon he passed one knife by stool, and on the following day two more, but the fourth knife never came away, nor gave him inconvenience. In March, 1805, in the course of a couple of days, he swallowed fourteen knives more; but on the following morning was attacked with constant vomiting and pain at his stomach, which compelled him to go to the hospital, and in the course of a month, "he was safely delivered of his cargo." In December of the same year, he swallowed on one day five, and on the next fourteen more. He was very ill the next day, and obliged to put himself under medical care, but without benefit till three months after, when having taken castor oil, he felt the knives "dropping down the bowels," and became easier, but was not aware of having passed any. In June, 1806, he vomited a knife-handle; in November he passed some fragments, and again in February, 1807. In August of the same year he was admitted into Guy's Hospital, where at first his account was not believed, but he held fast to his story, and as he suffered intense pain at the region of the stomach, and a hardness was thought to be felt, some credence was at last given, and his stools being noticed were found of a deep black, indicating an accumulation of ferruginous matter in his bowels. On examining the *rectum*, a portion of the knife was felt lying across it, but could not be extracted on account of the great pain he suffered in the attempts to grasp it. Various attempts were made to dissolve the knives, but without success, and at last, in March, 1809, he died in a state of great emaciation. On *examination*, one of the blades and one of the back springs were found in the intestines, the latter, four inches and a half long, had transfixed the colon opposite the left kidney, and projected into the cavity of the abdomen, while the other was stretching across the *rectum*, with one of its extremities actually fixed in the muscular *parietes* of the *pelvis*. No stool had, however, escaped, nor were there any signs of active inflammation. In the stomach were thirty or forty fragments, of which thirteen or fourteen were evidently blades, much corroded and diminished in size. They are all in the Museum at Guy's Hospital.

Another instance is also related by Dr. **Barnes**, of Carlisle (*b*), of a juggler, who, on 17th November, 1823. accidentally swallowed a table-knife with a bone handle, together nine inches in length. The account given by the man was, that "having offered for a small sum of money to swallow a table-knife, a new one was accordingly brought from a neighbouring shop. The method by which I pretended to swallow it was, to pass the handle and part of the blade down my throat, and hold the point of the knife fast with my teeth. When I was on the point of drawing it out again, some person, coming unexpectedly behind me, gave me a smart stroke on the back, the surprise of which caused me to lose hold of the point, and immediately the whole knife slipped into the stomach. I directly made very violent efforts to throw it up, but in vain, and the endeavours of the Surgeon were equally useless." The man immediately became very much alarmed, expecting instant death. Attempts were made with the fingers and with long forceps to seize the knife, but it was far beyond their reach, and could not be felt on the external surface of the stomach. Next day he complained of pain in his stomach, for which he was bled, and a clyster given; and afterwards, having pain in the left shoulder shooting across the chest to the stomach, he was bled again. Soon after the handle of the knife could be felt very distinctly by pressing gently on the navel, though slight pressure gave him considerable pain; but a single cup of tea or a little food of any kind distended the stomach so much that it entirely disappeared.

(*a*) Med.-Chir. Trans., vol. xii. p. 52, 1822.

(*b*) **Jameson's** Edinburgh Philosoph. Journ., vol. xi. p. 319, 1824.—**Hadfield**, A Statement of the Case of W. **Dempster**, a juggler, who died in consequence of having swallowed a Table knife. Middlewich. A pamphlet.

Various suggestions were made, and among others gastrotomy, but the patient would not consent to it. He was able to walk about a little during the day, and could sleep at night on his back, but not on either side. He was frequently squeamish and sick at stomach, and sometimes felt a severe twisting pain in that organ. He kept quiet till 28th December, when he left on his way to London, but died at Middlewich on the 16th January following. From the account it is very evident that he never laboured under any urgent symptoms, and seems to have been worn out rather by terror and anxiety. "On opening the belly," Hadfield says, "my first attention being of course directed to the stomach, I found the knife beginning to protrude through a gangrenous opening about two inches and a half from the beginning of the *duodenum*, on which part the knife had lain. After opening the stomach, I found that the point of the knife rested on that part of the greater curvature, almost exactly opposite to the *cardia*, and had likewise very nearly perforated the coats. * * * The handle of the knife was completely dissolved, the rivets had disappeared, and a considerable portion (at least one-third) of the blade also. What was left appeared exceedingly rusty and black." This knife is in the Museum of the Royal College of Surgeons. In the same collection are some knives voided by a soldier in St. George's Hospital.]

1744. Bulky bodies are most commonly retained in the stomach and at the ileo-colic valve. They may remain in the stomach a considerable time without causing symptoms, which, however, they easily produce in the intestinal canal, even if they be not fixed. The symptoms especially depend on the stoppage of the alimentary canal, or on the inflammation and injury which the foreign body produces by its peculiar form. In the first case symptoms of *ileus* arise; in the second, more or less severe *enteritis*. Oxidizable metals for example: copper coins produce no peculiar symptoms, as their oxidation, whilst resting in the alimentary canal, is exceedingly slow and not to that extent, which produces dangerous effects (*a*); indeed, in general, they are not long enough retained.

[In the College Museum there is a very interesting preparation from a woman who had long suffered under symptoms of gall stones, and at last died exhausted. On examination, the gall-bladder was found thickened, contracted, and both it and the liver intimately adherent to the *duodenum* and adjacent organs. Between the gall-bladder and *duodenum* was a large ulcerated ragged opening of communication, through which a large gall stone had passed, and, getting into the *ileum*, had blocked it up. Above this part the gut was distended with air and biliary fluid. In the Museum at St. Thomas's there is a portion of small intestine from a child, which is in two or three parts completely filled with lumps of hardened stool, in appearance resembling *album Græcum*, the result of quantities of carbonate of magnesia, which becoming entangled with the mucus of the bowel, had formed complete plugs of an inch or more in length.

The College Museum also possesses an example of cherry-stones lodged in the *cæcum*, which had been swallowed by a boy twelve years of age, at least sixteen months before his death, during which time he continually suffered from symptoms of chronic *enteritis*.

Langstaff (*b*) gives an account of a madman who swallowed a silver table-spoon in October, 1827. Soon after his health gradually declined. Although he lived abstemiously his digestive organs were disordered; he suffered from dyspepsia, and frequently complained of an acute pain in the region of the *cæcum*; and he persisted in declaring that all these symptoms were occasioned by the spoon he had swallowed. His account was disbelieved, especially as cautious examination of the belly was made without detection of any foreign body. He continued to suffer from the effects of pain in the situation of the *cæcum* and *colon*, and frequently said he felt the motion of the spoon. He was teased with diarrhœa, and the evacuations were often mixed with blood and pus. Symptoms of diseased liver came on, and were followed by *ascites* and *œdema* of the lower limbs. Under these circumstances Langstaff tapped him, drew off a bucketful of water, and, as he was "greatly emaciated, I was induced," says Langstaff, "to carefully examine with my hand if I could feel the spoon, when, to my astonishment, I detected a solid substance in the situation of the *cæcum*, which induced me to believe

(*b*) Catalogue of the Preparations, &c., constituting the Anatomical Museum of George Langstaff. London, 1842. 8vo. p. 228–32.

that it was the spoon he had swallowed." He died about twenty months after, and on *examination* it was found that "the mucous coat of the stomach, as well as the *duodenum*, *jejunum*, *ileum*, and *cæcum* were more vascular than natural, and there were evident signs of their having been ulcerated on different portions, and that nature had put a perfect stop to the ulcerative process, by uniting the boundaries to the submucous tissue. The greatest degree of mischief had been effected by the passage of the spoon through the ileo-cæcal valve, which was greatly dilated and the circumference thickened. The mucous coat of the *cæcum* was nearly destroyed by ulceration. The spoon was found in this intestine, with the bowl downwards, where it had formed a large sac, which prevented its passage into the *colon*." The preparation is now in the Museum of the College of Surgeons.]

1745. Pointed bodies, when they remain hanging in the walls of the intestines, excite inflammation to such extent as to produce union of the surface with the *peritonæum* or any other part, so that when suppuration takes place by the continued operation of a foreign body, it may make its way in different directions, and proceed either to the surface of the body, or even into any other cavity, as, for instance, into the bladder.

[In rare instances a foreign body will make its way through the walls of the intestine and belly, as in the case of the boy ten years old, from whom plum and cherry stones were discharged by an abscess communicating with the gut, and which are in the College collection.]

1746. In order to protect the stomach and intestinal canal against the effects of any such body, mucilaginous ensheathing food, and especially antiphlogistic treatment and purgatives, to hasten the passage of the foreign body through the alimentary canal, must be employed.

[This is the ordinary practice usually employed; but I am not sure that the late Sir **Francis Chantrey's** proceeding under similar circumstances is not preferable. He had accidentally swallowed the gold fastening of one of his teeth, and, being much alarmed, came to my friend **Green**, to consult with him about the matter, at the same time suggesting the propriety of eating freely of suet pudding, with the hope of entangling the little gold plate, and favouring its passage through the bowels. **Green** saw no particular objection to this proposition, and accordingly a due quantity of the medicinal pudding was swallowed. Nothing more was heard or seen of the tooth-plate, and whether passed or not is unknown, but it never gave any inconvenience.—J. F. S.]

1747. If there be a foreign body in the stomach, or in the alimentary canal, which will not pass off by the usual ways, and if it cause great danger to life, it must be removed by *cutting into the stomach* (*Gastrotomia*) or *into the intestine* (*Enterotomia*.) To decide on this very dangerous operation is always extremely difficult; it should only be undertaken when most positively called for by the situation of the foreign body, and on this point the symptoms are very doubtful. The intestine in which the foreign body is may be far from the wall of the belly. As long as no very severe symptoms occur, the operation should not be rashly decided on; and if they have already set in, the result of the operation is the more doubtful. Gastrotomy has, however, been performed successfully (*a*).

Delpech (*b*) considers that there never can be such certainty of the situation of a foreign body in the stomach and intestinal canal as to decide on gastrotomy or enterotomy. If there be a swelling, with fixed pain, the treatment should be confined only to a superficial cut, when the skin is distinctly pressed up by the suppuration, because there is no certainty to what extent union is effected, and whether extravasation of fæcal matter can be prevented.

There is a remarkable case in which a fork having been swallowed, excited suppuration, and by enlarging the opening of the abscess, was removed (*c*).

For the removal of poison from the stomach, **Read's**, or **Weiss's**, or **Graham's** stomach-pumps may be employed.

(*a*) **Baldinger's** Neues Magazin für Aerzte, vol. xiii. p. 567.—**Rust's** Magazin, vol. viii. pt. i.

(*b*) Précis Elémentaire, vol. ii. pp. 67, 68.

(*c*) Salzburg, Med.-Chir. Zeitung, July 1836, p. 14.

[**Barnes** (*a*) quotes from **Becker** the case of a young peasant, who on 29th May, 1635, whilst endeavouring to produce vomiting with the handle of a knife, let it slip from his fingers, and pass into his stomach. He was much frightened, but able to go about his usual occupation. It was, however, determined to remove the knife by operation, which was done on the 9th of July following, by a Surgeon and Lithotomist, named **Shoval**. "A straight incision was made in the left *hypochondrion*, two fingers'-breadth under the false ribs; first through the skin and cellular membrane, then through the muscles and *peritonæum*. The stomach subsided, and slipped from the fingers, which prevented it from being immediately seized; but it was at length caught hold of with a curved needle, and drawn out of the wound. A small incision was then made into it upon the knife, which was then easily extracted. The stomach immediately collapsed. After the external wound had been properly cleansed, it was united with five sutures, and tepid balsam poured into the interstices. Tents impregnated with the same balsam, and a cataplasm of bolar earth, the white of egg, and alum, were then applied." (p. 324.) Two sutures were removed next day, on the following day two more, but the fifth is not noticed. On the fourteenth day after the operation, the wound had healed. Dr. **Oliver** (*b*) saw this knife at Königsberg in 1685, and says it was six and a half inches long. The patient completely recovered.]

1748. If the stomach contain nothing but the foreign body, it must be moderately filled before proceeding to the operation, with mucilaginous fluid, for the purpose of bringing it near the wall of the belly (*c*). If by feeling, the position of the foreign body can be distinguished, the cut should be made upon that part: but under other circumstances, upon the front wall of the stomach, an inch below the sword-like process of the breast-bone, to an inch and a half above the navel, about three quarters of an inch to the left of the white line, that the cut may be between the great and little curvature of the stomach. The wall of the belly is to be cut through with some careful strokes of the knife; and then the stomach being laid bare, search is made for the foreign body, and a knife thrust into the stomach at the proper place, and the wound enlarged with a button-ended bistoury. The foreign body is then to be sought for with a pair of forceps introduced upon the forefinger of the left hand, taken hold of, and drawn out. The further treatment must be according to the rules already laid down for wounds of the stomach (*par.* 541.)

Hevin also proposes piercing the front wall of the exposed stomach with a grooved trocar, and to enlarge the wound upon it right or left.

1749. In enterotomy, the wall of the belly should be cut into where the foreign body is distinguishable, though, if possible, on that part where the epigastric arteries can be avoided, search made with the finger for the position of the foreign body, the intestine containing it drawn into the wound, and then sufficiently cut into for the removal of the foreign body. The further treatment is the same as in wounds of the intestine (*par* 529 and the following.)

Cutting into the intestine has been proposed for stricture and closure of the large intestines, for unrelievable collection of stools, for *ileus* and *volvulus*, in which cases, an artificial *anus* may be at the same time formed (*par.* 1616.) Although in such cases the operation may be successfully performed (*d*), yet on account of the uncertainty of the cause, and of the actual seat of the disease, as well as on account of the symptoms, to a great extent, an unsatisfactory issue to the operation, is so probable (*e*), that practitioners are rarely inclined to it.

(*a*) Above cited.

V.—OF FOREIGN BODIES IN THE RECTUM.

Morand, Collection de plusieurs Observations singulières sur des corps étrangers, les uns appliqués aux parties naturelles, d'autres insinués dans la vessie, et d'autres dans le fondement; in Mém. de l'Acad. de Chirurg., vol. iii. p. 606.

von Walther, Beobachtung eines fremden Körpers von ungewöhnlicher Grösse im Mastdarme; in Journal für Chirurgie und Augenheilkunde, vol. i. p. 435.

1750. Foreign bodies may be introduced through the *anus* into the *rectum*, either voluntarily or accidentally, in making a careful examination for certain things; or bodies which have been swallowed, after having passed through the bowels, may remain a longer or shorter time in the *rectum*; the passage of the swallowed body, however, in general causes no difficulty, as it is involved in a thick mass of stool. If the foreign body in the *rectum* excite symptoms, they depend on its peculiar form or its great size.

[(1) **Phillips** (*a*) mentions the case of an old man brought into St. Mary-le-bone Infirmary, who was delirious, and complained of having a stick in his *rectum*, and being unable to sit up without pain; but as no other information could be obtained about it, and no stick could be detected on examining the bowel, it was believed he was labouring under some delusion. A clyster was however given, but no stick was passed. On the third day he died, and on *examination*, at six inches above the *anus*, was found the inferior extremity of a stick, which was about as thick as an ordinary indicator finger; it was covered with its bark, and carefully rounded at each end. Its superior extremity had passed through the sigmoid flexure of the *colon* into the peritoneal cavity to the extent of four inches. The *peritonæum* was highly inflamed through its whole extent, but there was very little thickening about the tissues in the immediate vicinity of the perforated point. There was no appearance of disease in the *rectum*."

McLaughlan (*b*) relates the history of a Greenwich pensioner, aged forty-nine, who having introduced an immense plug of wood fitted to the *anus*, for the purpose of stopping a *diarrhœa*, fell accidentally upon a stool, and forced it up into the gut. Eight days after he applied for assistance, having in the mean while suffered severely from continual efforts to void his stools and urine, which last was done with great difficulty. The whole belly was considerably enlarged, and felt knotty from the stools so long retained. The end of the forefinger could barely reach the plug on account of the inflamed and swollen state of the gut, which had begun to suppurate. The ordinary instruments were unavailing for its removal, and a peculiar pair of forceps were invented for the purpose, and fitted upon it with a screw. The operation was very painful, and required much force. In the course of a fortnight he completely recovered.

A case is reported by **Johnson** (*c*) of a man who died immediately after being admitted into King's College Hospital; he had been labouring under obstruction of the bowels for five days, having eaten a large quantity of peas on the previous day; and during the last three days had also suffered from retention of urine. During the whole time he had had severe pain in the belly, costiveness, and bilious vomiting; purgatives were given without relief; and when admitted he was much debilitated, his features pale and shrunken; skin cold, and pulse feeble. On *examination*, the bladder was found distended, its base nearly at the brim of the *pelvis*, and its top reaching to the navel. The intestines were distended with air; but the *rectum* contained upwards of a pint of gray peas, which had been swallowed dry and almost without mastication, and had not undergone any other alteration than becoming swollen; some were mixed with stool in the *colon*, but the greater number were on the *rectum*, where they formed a solid mass, occupying almost the entire pelvic cavity, pushing up the bladder and prostate, and compressing the *urethra*, so that there was considerable difficulty in passing the catheter.

(2) **Brodie** (*d*) mentions the case of a person who had obstruction of the *rectum*, caused by a piece of apple core which he had swallowed on the day previous. **Welbank** tells me that on a similar occasion he pulled out a piece of *vertebra* and rib about an inch and a half long, part of a mutton chop which had been unwittingly swallowed.]

1751. The symptoms occurring under such circumstances are, obstruction, or entire prevention of passing stools, very severe *tenesmus*, great

inflammation, and swelling of the inner wall of the *rectum*, extending to the neighbouring parts and to the bowels, violent fever, *tympanitis*, and the like. The danger is always great, and the foreign body must be removed as quickly as possible. The removal is often exceedingly difficult, on account of the seat and form of the foreign body, and the degree of inflammation and spasmodic contraction of the *sphincter*.

[Abscesses by the side of the *rectum* are occasionally formed by hard substances, which have been swallowed, making way through its wall. **Brodie** (*a*) mentions an instance in which a very large abscess was found; it was opened, and sticking across it was a long fish-bone, which he extracted. **Green** tells me another instance of a female, in whom the abscess was so distended with pus, that when punctured it flew across the room; from it part of the *pelvis* of a snipe was removed.

But still more serious consequences than abscess occasionally happen when a foreign body remains fixed in the *rectum*; it may cause complete closure of this gut, as in a case which occurred to **Coulson**. The woman, previously in good health, was thirty-four years of age, and between the fourth and fifth month of her pregnancy, when she was attacked with sickness, constipation, pain, and distension of the belly. These symptoms increased in severity, fæcal matter was rejected from the stomach, the belly became more distended, and no relief from the bowels could be obtained, injections which were attempted to be thrown up the *rectum*, being immediately expelled. She gradually sunk, and on the ninth day from the commencement of the attack, died. On *examination*, the *colon* was found exceedingly distended, especially its descending part, and between three and four inches from the *anus*, a foreign body, believed to be a small portion of fish-bone, found adherent to the lining membrane of the *rectum*, and in this situation pressed on by the gravid womb. Immediately below the bone, the gut was completely closed to the extent of three inches. The preparation is in the College Museum.]

1752. When the position of the body in the *rectum* has been ascertained by the introduction of the left forefinger oiled, a pair of polypus or stone-forceps are to be introduced upon it, the foreign body seized and withdrawn. The removal may be always facilitated by injecting oil into the gut. In violent inflammation, blood-letting should be resorted to, and in spasmodic contraction of the *sphincter*, suppositories, with the addition of extract of *belladonna* or *hyoscyamus*. In a case in which the size of the foreign body was very great, a pair of forceps with a movable lock were employed, so that each blade could be separately introduced (*b*). In case of a very frangible body, as glass and the like, in which danger was dreaded from its pieces, the hand of a child was employed for its removal (*c*). The use of the various anal specula can render easy the grasping foreign bodies; but the force accompanying the use of these instruments, renders them dangerous, if there be much inflammation. In these cases it is better to cut through the *sphincter ani*, and thereby relieve the obstruction which prevents the removal of the foreign body. (**Delpech**.)

Marchettis (*d*), in a case in which a swine's tail, with the thick end upwards, had been introduced into the *rectum*, used a hollow tube, which protected the inner membrane of the *rectum* from injury.

[**Custance** (*e*) mentions the case of a man who fell on an inverted blacking pot, and had the whole of it forced up the *rectum*. Attempts were made for an hour and a half to dilate the *sphincter*, and remove it with forceps, but in vain. The small end of an iron pestle was then introduced, till it touched the bottom, and being held there firmly, was struck with a flat iron. At the second blow, the pot was broken into several pieces, which were removed piece by piece with the forceps, or with the fingers. Next morning he laboured under severe intestinal inflammation, with incessant vomiting and excruciating pain over the whole belly; and he died at night. The pot was two inches and three eighths at the brim, an inch and a half at its base, and two and an eighth in depth.

1753. Foreign bodies usually get into the windpipe, when during the act of swallowing, the *epiglottis* is raised by speaking, laughing, and the like, or when they are thrown into the mouth. The symptoms produced depend on the obstructed passage of the air, and the irritation of the lining membrane of the windpipe. Immediately there occurs a severe convulsive cough, with danger of choking, with a whistling and rustling in the throat, which sometimes relaxes for a space; the patient points to the seat of pain with his finger, has more or less painful effort in swallowing and in breathing; his voice is altered and becomes hoarse, or is completely lost; by the obstructed return of the blood from his head, the face at last becomes puffy and bluish, the eyes start out, the veins of the neck are swollen, and above the collar-bones there appears an emphysematous swelling. These symptoms sometimes continue with the same violence, sometimes cease, but recur at irregular periods; occasionally only some of them diminish, considerable pain, oppression, and difficulty of breathing remain. The consequences specially to be feared from foreign bodies in the windpipe are, suffocation, if the entrance of the air be completely prevented; *emphysema* of the lungs if the position of the body prevent the escape of the air; inflammation of the windpipe and lungs with their outlets, and apoplexy from the collection of blood in the brain.

[**Porter** (*a*) well observes:—"This accident never happens at the time it is generally considered as most likely to occur, namely, in the act of swallowing. When a person is engaged in the performance of this function the root of the tongue is depressed, whilst

(*a*) Above cited.

the *larynx* is elevated; the *epiglottis* is thus mechanically thrown as a bridge across the *larynx*, and so effectually closes it that the smallest morsel, or even a drop of water, can find no admission. * * * But it is different when a man attempts to draw a full inspiration whilst any foreign body is within reach of the current of air about to pass into the lungs. At this time the *epiglottis* is raised, the *rima glottidis* is distended, and everything appears to favour the entrance of the air, and, of course, of whatever it bears along with it. Thus, a person holding a sup of wine in his mouth to enjoy the flavour, incautiously attempts to breathe, a drop of the fluid enters the *larynx*, it produces great irritation and the spasmodic cough that ensues throws it out with great violence, perhaps even through the nostrils." (pp. 184, 185.)

One of the most remarkable instances of a foreign body getting into the windpipe without passing through the *rima glottidis* is mentioned by De la Martinière (*a*). A child, nine or ten years of age, amusing himself with cracking a small whip, was suddenly seized with extreme difficulty of breathing, and soon exhibited all the symptoms of approaching suffocation. He complained, by gesture, of some impediment in the *trachea*. The Surgeons who saw him, aware that he had never been left alone, and that he could not have put anything into his mouth, did not suspect the existence of a foreign body impeding respiration." He was bled, the throat examined, and an œsophageal bougie passed, without making any discovery. The symptoms became more urgent, and De la Martinière saw him an hour after. "On examining the neck externally, I found," says he, "a small red spot on its fore part, like the middle of a flea-bite, immediately below the cricoid cartilage, and beneath it was felt deeply a little circumscribed ganglion as large as a lentil, corresponding to the red spot, and of unnatural brightness; the sensation could not have been more distinct through the thickness of the parts. I at once determined to cut through the skin and fat upon this spot. The finger having been introduced into the wound, and touching the tubercle, which was close to the windpipe, I deepened it with a second stroke of the knife, and laid bare the cartilaginous rings of that tube. I felt with my nail an irregularity, projecting at least a line above its convexity, and endeavoured in vain to seize it with the dressing forceps. Luckily I had with me a pair of hair-nippers, and with these caught hold of the body, which I drew out; and, to my great surprise, found it to be a large copper pin without a head, about an inch and a quarter long, which had pierced through the windpipe from left to right." The child got well in a few days.]

1754. The difference of the symptoms depends on the particular seat, form, and condition of the foreign body. If situated in the *rima glottidis*, and completely closing it, the patient is suffocated, if not quickly relieved, or the foreign body do not change its place by the violent inspiration and expiration, which, however, is rarely the case, on account of the spasmodic contraction of the *rima*. If the *rima* be not completely closed by the foreign body, violent convulsive cough comes on, and the patient points to the seat of the body with his finger. A foreign body, if not of large size, may remain lying in either of the laryngeal ventricles. Its symptoms are at first less severe, but the continued residence of the foreign body will, in the end, be fatal (1). If it be loose in the windpipe, it moves up and down with every inspiration and expiration; symptoms come on at intervals; the pain is severe; changes its place; the cough is frequent and convulsive, so that, in very rare cases, the foreign body is coughed out; danger of suffocation occurs if it be forced up against the *rima glottidis*. Foreign bodies rarely drop into either *bronchus* (2). Pointed rough bodies cause violent symptoms; the mucous membrane of the windpipe inflames, swells, and the passage narrows where the foreign body is fixed. The same happens with those bodies which swell with moisture. In rare cases the foreign body, after remaining a long while in the air passages, and producing symptoms of *phthisis*, is thrown out, and the case terminates satisfactorily (3).

[(1) A foreign body, to be lodged in the ventricles of the *larynx*, must be extremely small; and I apprehend such as are generally described as so situated are not so, but only

---

(*a*) Mém. de l'Acad., above cited.

in the body of the *larynx*, of which there are two examples in the Museum of St. Thomas's Hospital. In one a piece of mussel-shell lies lengthways in the left side of the *larynx*, with its upper end jammed into the base of the *epiglottis*. I cannot get more information of it than that the child lived a fortnight after the accident. The other, a case related by **Bullock** (*a*), was a girl of six years, who swallowed a pebble. "She was seized with a most violent convulsive cough, so that she became black in the face and was nearly suffocated; the paroxysm continued for half an hour and then subsided. The throat was examined, and an œsophageal probang introduced, but without, however, discovering any extraneous body. The three or four following days the child merely complained of a sense of soreness in the throat with nausea, which was accompanied by occasional slight paroxysms of cough with a copious mucous expectoration; she was also hoarse, but had no pain or difficulty in deglutition. Aperients and an emetic were prescribed; she was not benefited, and, as she still persisted that the stone remained in the throat, was again, on the fifth day, very carefully examined, yet there did not appear to be any evidence of its existence either in the *œsophagus* or *trachea*." As she had not had hooping cough and was constantly playing with children who were labouring under that disease, it "appeared to warrant the conclusion that no foreign body had passed either into the *œsophagus* or *trachea*, and that the cough was among the first symptoms of a severe form of *pertussis*. At the end of the fifth day she had marked symptoms of inflammation of the mucous membrane of the *bronchi*, namely, cough, generally occurring in paroxysms six or seven times a day, attended with a kind of whooping inspiration and a copious expectoration of tenacious mucus; the hoarseness was likewise increased, while over the *trachea* and upper part of the chest there was a loud mucous rattle, which was in part sonorous." Leeches, and calomel, and antimony were used for some days, and in a month from her first attack she was stated to be "quite well," having regained her flesh and healthy appearance. A fortnight after this, however, "she was attacked with symptoms of *pneumonia*," and she died in twelve days, "eight weeks from the supposed accident; but from the time she was reported quite well to the day of her death there was no return of the convulsive cough nor any uneasiness about the throat. On the day of her death, however, she again said she could still feel the stone, and in the same place as at first. *Examination.*—On laying open the *larynx* and *trachea* a quartz pebble was exposed, lying partly in the cricoid cartilage and partly in the *trachea*, of the size of a horse bean, of irregular figure and smooth surface; it was retained in its situation by a layer of apparently organized lymph of very considerable thickness. On removing the stone the mucous membrane was in a state of ulceration (and the front of the thyroid and cricoid cartilages bare.—J. F. S.) The calibre of the tube was so nearly obstructed by the presence of the stone and lymph as to render it difficult to pass an ordinary-sized probe downwards. The whole of the mucous membrane of the *trachea* was thickened and its vessels congested. About a pint of turbid fluid was in the right *pleura*, containing flakes of adventitious membrane, with which the *pleura pulmonalis* of that side was also covered. Nearly the whole right and the lower part of the left lung were in the several degrees of hepatization and purulent infiltration. (p. 952.)

(2) When the weight of the foreign body has carried it low down into one of the *bronchi*, most commonly the right on account of its larger size, as first noticed by **Key**, it may block up the passage so completely that no air, or but little, can pass into the lung below it, and consequently it remains fixed by its own gravity, causing pain in the chest opposite the part where it is lodged, which is increased on deep inspiration, and is accompanied with "a catching." Violent cough and a disposition to vomit, or actual vomiting, occur immediately after the accident, but after a time subside, and an occasional dry cough comes on at irregular periods, and in the intervals the patient may be tolerably well and able to follow his ordinary occupation, or the symptoms may become more urgent, may be accompanied with repeated attacks of *hæmoptysis* and terminate in *phthisis*, even although the foreign body have been coughed up after having been retained weeks or months. Some remarkable cases of this kind will be presently referred to.

(3) The time which a foreign body, after the first severe symptoms have passed by, may remain lodged in the air passages varies very considerably. The longest period of which I am aware is that of the female mentioned by **Sue** (*b*), who when in her ninth year, had the rump-bone of a pigeon slip into her windpipe; she became subject to attacks of *hæmoptysis* and other symptoms of pulmonary disease, but without wasting, till her twenty-fourth year, when she began to decline rapidly. Two years after she threw up the bone in a violent fit of coughing; but she died eighteen months after with

---

(*a*) London Medical Gazette, vol. xviii. 1836.

(*b*) Mém. de l'Acad. de Chirurgie, vol. v. p. 533.

profuse purulent expectoration. Dupuytren (*a*) gives an account of a man who lived ten years, after a small coin had got into his air-tube, and on examination it was found embedded in a tubercular cavity in the lung. Louis (*b*) also relates another case, in which after swallowing a louis-d'or, a man lived six years and a-half, and then died with his right lung completely destroyed by suppuration. My friend Sutton, of Greenwich, has mentioned to me a case of *hæmoptysis*, which he attended many years since. The man had frequent attacks for more than a twelvemonth, from each of which, however, he rapidly recovered. Upon the last occasion, he was summoned suddenly to see the man, who was said to be in a dying state. On his arrival he found the patient had had a very severe attack of *dyspnœa*, and threatening suffocation, from which, however, he had been immediately relieved on rejecting from his windpipe a common lathe nail, much corroded. The man was a plasterer by trade, and now remembered that some time before first requiring Sutton's assistance, he had swallowed a nail whilst lathing a ceiling, but had thought no more about it till it was thrown up. He died some years after of diseased lungs. Dr. Paris (*c*) relates the case of a girl twelve years old, who "having put a small cowrie shell in her mouth, was seized with a violent choking fit, in consequence of its having been supposed to have gone the wrong way in the act of swallowing it. The spasmodic paroxysm was described as most alarming, and continued for several seconds, which induced her father to thrust his finger with considerable force down her throat, which afforded immediate relief, and therefore convinced him that he had thrust the foreign body into the *œsophagus*, and that it had passed into the stomach. * * * In the course of four or five days a slight cough came on, but it was not characterized by any symptom which would lead to the suspicion of it having been provoked by the presence of any foreign body in the air passages, and this opinion was confirmed by its speedily yielding to the ordinary treatment." Between three weeks and a month after she had "a return of the cough much more violent than usual, and accompanied with slight *hæmoptysis*. This, however, again subsided, and she remained for many months in perfect health; her breathing was never disturbed, she indulged in her usual active habits and daily exercise, and declared that she was perfectly well. * * * About twelve months after, she had danced at a ball during the whole evening, and at its conclusion, in the act of moving briskly, she was suddenly attacked by a violent spasmodic cough, which threatened suffocation, when by a sudden and convulsive expiration, a substance was ejected from her mouth with such force as to be carried to a considerable distance. This proved to be the remnant of the shell, the animal principle of which had disappeared, and its earthy matter alone remained." (pp. 116, 17.) In the younger Travers's case (*d*), a girl of six years, who was suddenly thrown back whilst eating cherries, "was immediately seized with a violent fit of choking and every symptom of impending suffocation. This condition lasted an hour, and then she fell asleep." On the next day she had some spasmodic pain in the chest, and on the following "morning the breathing was very difficult, and other symptoms of inflammation present," which were relieved by blood-letting, a calomel and jalap purge, and calomel and opium. On the afternoon of the fourth day "she had a violent convulsive seizure, with cough, small quick pulse, a livid surface, suffused eye, and every sign of threatened suffocation. It was stated in evidence of the violence of the spasm, that the stools and urine 'flew' from the child during these attacks." She grasped and pulled her throat in a peculiar manner, "crying in a half whisper 'take it out! take it away!' The spasm subsided after two hours' continuance," and a few hours after she was so tranquil as to lead to the belief "that no stone could have passed into the *trachea*." In the middle of the following day the fit recurred, with "violent jactitation and abundant flow of frothy mucus from the mouth. When it had subsided, the probang was introduced, and the child swallowed with greater facility." On the seventh day there came on a similar attack; on the thirteenth, and from that time daily, till the nineteenth day, when Travers saw her, and she had then "frequent paroxysms of croupy cough, attended by great restlessness and the peculiar grasping of the throat." Under these circumstances, he performed tracheotomy; but the stone was not thrown out; the breathing, however, became tranquil, and the cough also ceased. It returned, however, on the twenty-sixth day, but less severely. About six weeks after, the wound, which had been tented healed, and soon after "the child coughed incessantly, had night sweats, with loss of strength and appetite." In this condition she continued till the ninety-sixth day after the accident, when she threw out "the stone, together with a table-spoonful of pus, during a violent paroxysm of cough; having expectorated pus in small quantities for many days previous. From this time the cough never returned, and the general health was soon re-established." (p. 108–12.)

(*c*) Med.-Chir. Trans., vol. xxiii. 1840.

(*d*) Ibid.

1755. As foreign bodies in the *œsophagus* produce the same symptoms as those in the windpipe, it is always necessary, by examination of the throat, by the introduction of a sound, with a piece of sponge upon its end, to be sure of the *œsophagus* (1).

Foreign bodies are only in very rare instances, thrown out by violent coughing: on this account a severe emetic or artificially excited sneezing increase the danger (2).

The only remedy for the certain removal of the foreign body is *opening the windpipe, (Bronchotomia, Tracheotomia,)* or *opening the larynx, (Laryngtomia.)* This operation must be undertaken as quickly as possible, because if put off, such symptoms as violent inflammation of the lungs and windpipe, *emphysema* of the lungs and the like arise, which even after the removal of the body may cause death. The operation is in all cases required, where suffocation presses, or an asphictic condition has set in; further, if dangerous symptoms occur from time to time, and the foreign body be observed rolling up and down in the windpipe; or if fixed pain point out its exact seat. But if the patient be free from all these symptoms, and the seat of the foreign body cannot be discovered, we must wait till there are symptoms of change in its situation, and a possibility of its removal.

[(1) In reference to this subject STOKES (*a*) mentions one instance in which a piece of money lodging in the *œsophagus* produced croupy breathing and laryngeal symptoms. And in his Lectures he used to speak of another case in which such symptoms were produced by a foreign body (a plum-stone) in the *œsophagus*, that his first impulse was to perform tracheotomy with his penknife. An œsophageal bougie was, however, introduced, and the substance having been pushed into the stomach, the symptoms ceased, and a day or two after the plum-stone, with which the child had been known to be playing previous to the accident, was voided by stool (*b*).

(2) Occasionally it may happen that although violent fits of coughing having failed to expel the foreign body from the windpipe, yet by some accidental change in the patient's position, the foreign body is removed from its lodging place, and is then thrown up with little effort. Such seems to me the explanation of COCK's case (*c*) of a sixpence slipping down the throat, and at first lodging in the *larynx*; "violent coughing, wih the most distressing sense of suffocation, immediately took place, and during the paroxysm he threw up a quantity of blood. On his admission he was still struggling for breath, coughing incessantly, and suffering great pain and irritation, which he referred to the *larynx*, where the coin appeared to have lodged." Shortly after "the sixpence had left the *larynx*, and descended into the *trachea*; its change of position being immediately followed by an abatement of the previous urgent symptoms. He still coughed almost incessantly, stated that he could feel the sixpence moving up and down the windpipe, and complained of pain and soreness in the chest in the seat of the right *bronchus*, and also just below the *larynx*." Towards the end of the same evening the symptoms subsided, and he went to sleep. On the following day he was in much the same state, and "as long as he remained calm and quiet, he complained of nothing but a feeling of general soreness along the *larynx* and windpipe." The same evening the sixpence was thrown out without surgical aid. "I was asleep," said the patient, "and dreamed I was drinking a pot of porter, and the attempt to swallow it made me cough. I awoke, and found the sixpence in my mouth." COCK observes:—"It is perhaps worthy of remark, and not destitute of practical interest, that the foreign body, which had retained its position during the most violent expiratory efforts, should at length be ejected, at a period when the muscles of the *glottis* were probably in a state of quietude, and being taken unawares, allowed its expulsion, under a gentle act of coughing." (pp. 554, 55.)]

1756. Opening the *larynx* or windpipe is also required to assist the entrance of the air into the lungs, when it is obstructed under any other circumstances, and suffocation is dreaded; in great swelling or other

---

(*a*) Above cited, p. 265.

(*b*) WELLS; in Dict. of Pract. Surgery, vol. i. p. 516. (*c*) Medical Gazette, vol. i. New Series, 1845.

degeneration of the structures about the throat; in diseased changes of the *epiglottis;* in great swelling of the tongue, if the danger cannot be relieved by bleeding, scarification, and the like; in fracture of the thyroid cartilage, if the dislocated pieces cannot be otherwise brought into place; in inflammation of the *epiglottis (Angina laryngea)*; when foreign bodies are in the *œsophagus*, and cause suffocation; in compression of the windpipe by tumours; in gun-shot wounds of the throat, which, on account of the great swelling, are attended with danger and suffocation; in drunken or suffocated persons; in croup, if the membrane be loose and cannot be coughed up.

According to **Desault** (*a*), in the greater number of these cases in which it is only necessary to assist the entrance of the air, the introduction of an elastic tube through the nostril renders the operation superfluous. No other person, however, but **Desault** holds this notion. **Samuel Cooper** (*b*) objects to it in drunkards and suffocated persons, and considers opening the windpipe to inflate the lungs, most efficient. However, the benefit of cutting into the windpipe, undertaken in this spirit, is not supported by precise reasoning.

In *Angina laryngea*, which is characterized by difficult breathing, with pressing suffocation, very hoarse and only whispering voice, and frequently accompanied with pain in the *œsophagus* and difficulty in swallowing, without apparent swelling and redness of the throat, the operation must not be long delayed, if relief be not soon afforded by general and local blood-letting, blisterings, and the like (*c*). In *Angina membranacea*, laryngotomy and tracheotomy are generally useless, because the mass blocking up the air-tube, is not merely in the *larynx*, but extends through the whole windpipe and even into the *bronchi* (*d*). In more modern times, however, many cases have been published in which this operation has been successful.

Nevermann (*e*) has collected all the cases of *laryngitis* and *trachæitis*, in which tracheotomy has been performed; and the result is that out of one hundred and forty cases, twenty-eight have been cured, and one hundred and twelve died.

Bretonneau (*f*) considers that tracheotomy can only terminate favourably, if the opening be made moderately large between the thyroid gland and the breast-bone, and the free entrance and escape of the air maintained by a sufficiently large and wide canula. At the same time he introduces calomel dry, or moistened with water, through the wound into the windpipe. In one case he succeeded.

Trousseau (*g*) also recommends the introduction of a thick catheter, and scraping out the windpipe with a probang, and dropping in a watery solution of nitrate of silver, four grains to a dram of water. **Gerdy** (*h*) also advises the introduction of a weak solution of lunar caustic.

[**Kirby** (*i*) is decidedly opposed to bronchotomy for croup; he says:—"I have performed the operation myself on the child, and have seen it frequently done by others, and in no one case has the life of the patient been saved." (p. 63.)]

1757. The proceedings vary in laryngotomy and tracheotomy, in reference to the special object desired, according as the entrance of the air is to be assisted, or a foreign body removed.

1758. In laryngotomy, after placing the patient's head in such a position as that his uneasiness shall be least, and the front of the neck free and accessible, the skin is to be moderately stretched on both sides with the fingers of the left hand, and the *larynx* at the same time fixed; a cut is then made lengthways, about an inch in length, the middle

(*i*) Observations, cited at the head of article.

of which corresponds to the crico-thyroid ligament. A second cut divides the cellular tissue between the sterno-hyoid and sterno-thyroid muscles, and lays bare the crico-thyroid ligament; the bleeding must be stanched with a sponge dipped in cold water. The *larynx* is then to be fixed with a finger on each side, and the forefinger of the same hand placed on the upper third of the ligament; after which a lancet is thrust in, and a wound of sufficient extent made, which is to be kept open by inserting lint between the angle of the skin and of the muscular wound, and the whole covered with gauze, and the patient allowed to bend his head towards the chest.

This method appears preferable to using the tracheotome and introducing a tube into the aperture made in the crico-thyroid ligament, for the tube always excites inconvenient, and frequently unbearable irritation, is frequently stopped up, and cannot be properly fastened. The cases in which cutting into the windpipe is performed are urgent, and the tracheotome cannot be sufficiently commanded. If the opening into the crico-thyroid ligament be insufficient, the cut must be lengthened through the cricoid cartilage. For the purpose of effecting expectoration, if much tough mucus collect, the wound must occasionally be held with the fingers, and the patient allowed to cough. If a canula be used, it should always be sufficiently large.

For the purpose of avoiding an often not inconsiderable arterial branch upon the crico-thyroid membrane, we must feel with the finger if the membrane be quite bare, and when it is exposed, we must endeavour to avoid it, for which purpose the membrane is to be divided transversely at the upper edge of the cricoid cartilage.

[Some persons are in the habit of introducing a tube into the *larynx* after having opened it. This as a general rule is quite unnecessary, as if there be any fear of the wound closing before the air can recover its usual course through the *rima glottidis*, it is better to cut out a piece of either the laryngeal or tracheal cartilage, as may be, according to Lawrence's recommendation. And it is also improper, as a fistulous opening will be formed, which on the subsequent removal of the canula, may contract so as to require a second operation, and often cannot be done without. If, however, such practice be adopted, it will be necessary that the instrument should be taken out from time to time to ascertain that it has not been corroded; for if not, it may break, and the part within drop down the windpipe, whilst that without falls from the wound, without notice. A case of this kind was admitted into St. Thomas's Hospital in December, 1844; a tube had been introduced about two and a half years previously, and on the morning of his admission whilst walking along the street, it slipped out broken. No symptoms of consequence, however, appeared till towards evening, when the breathing became difficult, and attended with a whistling noise; the veins of his head and face distended, and the surface covered with cold perspiration. My colleague and assistant, the younger Travers, therefore, thought it necessary to pare the edges of the opening, and dilate it upwards and downwards upon a director. Some blood running into the windpipe caused violent expirations, and in one of them two fragments, which formed the remainder of the canula, were expelled, surrounded with a clot of blood, and the relief was immediate. Another canula was introduced. The patient did well; and the broken corroded instrument is in St. Thomas's Museum.

Occasionally it happens that after a severe cut throat, the aperture remains, from some cause or other, fistulous; and as the scar contracts, the passage for the air is so narrowed as to cause great difficulty of breathing, and require surgical aid. I had a case of this kind some years ago, in a Hindoo woman, who, in her voyage to this country, had attempted suicide, and nearly cut through the *larynx*, between the thyroid and cricoid cartilages. She had been very refractory, and the skin had turned over the lower edge of the wound, and become connected wilh the back of the organ, so as materially to diminish the passage, and cause her breathing to be very laborious, and with a loud hiss. As from the account given, these symptoms were daily becoming worse, I cut through the front of the cricoid cartilage vertically, and inserted a short but pretty wide tube, through which she breathed freely and did well, leaving the house some time after to return home.—J. F. S.]

1759. If laryngotomy be undertaken for the removal of a foreign body, the crico-thyroid ligament is, after the bleeding has been stanched, to be cut through its whole length, from the thyroid to the cricoid cartilage; and if this be insufficient to allow the foreign body to be removed or withdrawn through it, a director somewhat curved is to be introduced, by means of which a button-ended bistoury is passed in, and the thyroid cartilage sufficiently divided upwards in its centre, or the cricoid cartilage, and the upper part of the air-tube so far cleft as the removal of the foreign body may seem to require.

1760. After the opening is made, if the edges of the wound be gently drawn apart with blunt hooks by the assistants, the foreign body usually appears and is thrown out by coughing; but if this do not happen, its position must be sought with due care, and it must be removed with straight or curved forceps. The treatment, after removal of the foreign body, must be precisely similar to that already laid down for longitudinal wounds of the windpipe. (*par.* 467.)

1761. In tracheotomy, where the entrance of the air merely is to be assisted, a cut should be made through the skin and muscle on the mesial line of the windpipe, beginning below the cricoid cartilage and continued down to the edge of the breast-bone. The edges of the wound are to be held asunder with blunt hooks, the blood sopped up with a moist sponge, the cellular tissue and vascular net upon the third and fourth cartilaginous rings divided, and thus the windpipe laid bare. Bleeding is stanched by cold water, or, where possible, by tying the vessels; the lobes of the thyroid gland, which are a little in the way, are to be turned aside, and two or three rings of the windpipe divided vertically. The further treatment is the same as after opening the *larynx*.

The same reasons against the use of the tracheotome and the introduction of a tube, which have been already given (*par.* 1758) also apply here. LAWRENCE (*a*) advises, if after opening the windpipe, the introduction of the tube cannot be effected, to cut off half an inch through the cartilage, and to remove a small slip from the edges of the wound, so that the opening may continue to gape.

1762. If tracheotomy be performed for the removal of a foreign body, the air-tube must be exposed and cut into in the way just described, only the size of the cut must be proportioned to that of the body to be removed. The removal itself must be managed as in laryngotomy.

[When the foreign body is lodged in the *bronchus* its removal should be first attempted by reversing the patient's natural position, and placing him upright, or nearly so, with his head downwards, and then striking his back or shaking the body smartly, by which it may be hoped the foreign substance will move from its situation, and, dropping through the windpipe, be ejected at the *rima glottidis*. Of the two very interesting cases in which this practice was successfully adopted, BRODIE's patient (*b*) had first attempted it on the sixteenth day after the accident, by "placing himself in the prone position, with his *sternum* resting on a chair, and his head and neck inclined downwards, and, having done so, he immediately had a distinct perception of a loose body slipping forward along the *trachea*. A violent convulsive cough ensued. On resuming the erect posture he again had the sensation of a loose body moving in the *trachea*, but in an opposite direction, that is, towards the chest." The experiment was repeated six days after, more completely; "he was placed, in the prone position, on a platform, made to be movable on a hinge in the centre, so that on one end of it being elevated, the other was equally depressed. The shoulders and body having been fixed by means of a broad strap, the head was lowered until the platform was brought to an angle of about 80 degrees with the horizon. At first no cough ensued; but on the back, opposite the right *bronchus*, having been struck with the hand, the patient began to cough violently; the half-sovereign, however, did not make its appearance. This process was twice repeated with no better result; and on the last occasion the cough was so distressing, and the appearance of choking was so alarming, it became evident it would be imprudent to proceed further with this experiment unless some precaution were used to render it more safe." Tracheotomy was therefore determined on two days after, and "in proposing this," says BRODIE,

---

(*a*) Above cited, p. 249.

(*b*) Above cited.

"we had a twofold object; the one, that if the coin were lodged in any part from which it might be safely extracted by the forceps, this method might be had recourse to; and the other, that, if relief could not be obtained in this manner, the artificial opening might answer the purpose of a safety valve, and enable us to repeat the experiment of inverting the body on the movable platform without the risk of causing suffocation." The operation "being completed, some attempts were made to reach the coin with the forceps introduced through the opening. The contact of the instrument with the internal surface of the *trachea*, however, induced on every occasion the most violent convulsive coughing. The coin was not seized, nor even felt." The attempt was therefore given up for the time, and repeated five days after with no better success. He was left quiet for ten days to recover from the exhaustion he suffered, and the probe was passed occasionally into the wound to keep it open. At the end of this period, on the thirtieth day after the accident, "the patient having been placed on the platform, and brought into the same position as formerly, the back was struck with the hand; two or three efforts to cough followed, and presently he felt the coin quit the *bronchus*, striking almost immediately afterwards against the incisor teeth of the upper jaw, and then dropping out of the mouth. A small quantity of blood, drawn into the *trachea* from the granulations of the external wound, being ejected at the same time. No spasm took place in the muscles of the *glottis*, nor was there any of that inconvenience and distress which had caused no small degree of alarm on the former occasion. (p. 288–91.) The case did well. MACRAE (*a*) did not make any opening into the air-tube of his patient, but, on the third day after the mishap, had him "strapped securely to a common chair, that he might be easily suspended from the rafters of the roof, with his head downwards, in order that his chest might be conveniently shaken by a rapid succession of sudden smart jerks, and that the weight of the bullet might favour its escape from its seat in the lungs. He was kept depending as long as he could endure such an uncomfortable position, and then placed in the horizontal posture for a few minutes to rest. When sufficiently recruited he was hung up again. Upon being taken down the first time he described the pain in his breast as having moved nearer to the top of his chest; and during the third suspension he joyfully exclaimed, "thanig à! thanig à!" ("it has come! it has come!" in the Gaelic language,) immediately after a smart shaking and a few convulsive retching coughs, and spat the little bullet from his mouth. The diameter of it is three eighth parts of an inch, having its surface ruffled by the chewing it underwent previously to slipping into the windpipe. He felt immediate relief from every uneasy feeling, except the dry cough and deep-seated pain in his breast, which continued rather sharp for two days, after which, and a dose of laxative medicine, he found himself restored to his former health, and by the end of the week pursued his usual avocations on the hill." (pp. 421, 422.)

If this mode of treatment be insufficient to dislodge the foreign body from the *bronchus*, it will be necessary to attempt its removal by opening the windpipe and drawing it out with forceps. This operation was first performed, and successfully by LISTON in 1833 (*b*), on a female of thirty-eight years, who "got a piece of mutton bone entangled in the *glottis*, whilst eating some hashed meat. By a great effort, during a fit of threatened suffocation, she succeeded in dislodging it; but it passed downwards into the *trachea*," * * * and lodged permanently under the right sterno-clavicular articulation. An attack of *bronchitis* supervened, followed by cough and expectoration, and the inflammatory attack was repeated several times; from one of these she had just recovered. * * * The inspiration was somewhat noisy, and there was some degree of peculiar sonorous râle perceived on applying the ear to the chest at the point described as where the foreign body had become fixed. The operation was performed; one pair of forceps opening laterally were introduced; a hard substance could be felt, but not grasped; the patient was re-assured, and allowed to recover the effects of the exploration and attempt to seize it. Another instrument with the blades differently arranged, was then passed down the tube, at least three or three and a half inches, and the bone immediately seized and extracted. * * * The result of the case was most satisfactory. The length of the forceps was seven inches. (pp. 415, 16.) The second operation was performed also successfully by DICKIN, of Middleton, near Manchester, in 1832 (*c*), on a boy of eight years, who having "found a bell button, which he placed in his mouth, and during the act of jumping, it passed backwards into the windpipe. He instantly fell down, to all appearance in a state of suffocation, and was taken home, a few yards distant, making the most violent efforts to respire; after which his breathing became easy, but with

(*b*) DUNCAN; in Lancet, 1833, 34, vol. ii. p. 419. —Also LISTON's own notice of it, in his Practical Surgery; from which I have quoted.

(*c*) LISTON; just cited.

repeated dispositions to cough, which alarmed him, threatening instant suffocation. * * * He complained of a sense of constriction across the chest, * * * had fits of coughing, which came on at intervals of two or three hours, during which he was comparatively easy. The face presented a purplish hue, with great anxiety depicted." Three days after, on examining the chest, its "appearance was most remarkable. On the right side a loss of symmetry, with evident depression and altered action in breathing. The stethescope indicated no respiratory murmur; whilst on the left side there was the plump symmetrical beauty of a youthful chest, with the common action of that side in respiration. * * * On the sixth day the cough ceased, and also the fits of suffocation, which evidently indicated a fixed position of the foreign body." On the tenth day it was determined to perform laryngotomy between the cricoid and thyroid cartilages; which done, a pair of forceps invented for the purpose were introduced, and "acted as a sound, for on their introduction DICKIN detected the presence of a metallic body. They were introduced again without the slightest inconvenience to the patient (at least apparently so,) when again the point came in contact with the button, which was laid hold of, and removed in their grasp. * * * For several days a considerable quantity of muco-purulent matter was discharged through the wound, having accumulated around the button in the *bronchus*." (pp. 419, 20.) In a fortnight the boy was well, and returned to school.

If after opening the *larynx* or windpipe, the foreign body be jerked up into the wound, or shot through it, immediately after the free admission of the air, the windpipe be examined by passing a straight sound through it towards the chest, and no obstruction be found it will be right to examine the *larynx* itself, and the *rima* by passing a sound upwards into the throat. The necessity for doing this is seen from the case related by PELLETAN (*a*), in which a person suffered severely from having a portion of tendon of veal lodged in his throat; it was so large that it was presumed to have lodged in the *œsophagus*; no relief, however, was obtained by the introduction of instruments, and PELLETAN therefore opened the *larynx* by division of the thyroid cartilage, and on introducing his finger, unawares thrust the tendon upwards, after which with the probang it was forced down the throat, and the patient recovered.—J. F. S.]

1763. If bronchotomy be considered in reference to the three parts at which it may be performed, namely, on the thyroid cartilage, on the crico-thyroid ligament, and in the windpipe, the following circumstances must be borne in mind with reference to the special object of the operation.

In cutting through the thyroid cartilage, it may be feared, in addition to the possibility of it being ossified, and therefore difficult or incapable of being cut through, that the laryngeal ligaments may be wounded, and that in those cases in which the operation is undertaken, on account of a swollen and thickened condition of the inner membrane of the *larynx*, the air may not obtain a sufficient entrance; the voice also may remain for a long while, or even permanently hoarse, if the operation be undertaken in the *larynx*. (PELLETAN.)

Tracheotomy, to wit, the cutting into the windpipe from the cricoid cartilage to the upper edge of the breast-bone, is always dangerous; the cut always interferes with the anastomoses of the thyroideal arteries; if the arterial *plexus* of the thyroid gland be wounded, it is very difficult to stanch the bleeding, and the blood flowing into the windpipe causes violent cough. In thick-necked persons the operation may be extremely difficult, and even impossible. In children it is always very difficult, on account of the thickness of their neck and the depth of their windpipe (1). If there be an *arteria thyroidea ima*, it will certainly be wounded.

Opening the crico-thyroid ligament, and enlarging the wound downwards through the cricoid cartilage, and the first two or three rings of the windpipe *(Laryngo-tracheotomia)* seems therefore to be the most advantageous proceeding, both where it is desired to assist the entrance of the air, and to remove a foreign body, because by this method the arterial

---

(*a*) Clinique Chirurgicale, vol. i. p. 13.

plexus and the deep position of the windpipe are best avoided. Even if the foreign body be lower down in the windpipe, it may be either brought near the opening, by breathing or coughing, or it may be with proper care taken out with a blunt curved director or with the forceps. If it be found fixed in the *larynx*, the cut may even be extended from the crico-thyroid ligament along the middle of the thyroid cartilage. By this mode of proceeding, then, the object of the operation is best attained in all the conditions of the disease which have been mentioned (*par.* 1756); and a deeper cut into the windpipe would be required only in those cases where the situation of a foreign body in the *œsophagus*, or other tumours, which compress the windpipe may render it necessary.

(1) According to ALLAN BURNS (*a*), the position of the thyroid gland should be determined by the cricoid cartilage, and in children the space between this gland and the upper part of the breast-bone is great, therefore tracheotomy is easier.

1764. The varieties observed by ALLAN BURNS in the vessels of the neck always renders careful observation necessary during the course of the operation. He found the *arteria innominata* near the under edge of the thyroid cartilage, and even the carotid itself crossing the windpipe.

KELL, Beobachtungen über Froschgeschwülste; in VON GRAEFE und VON WALTHER's Journal, vol. xxvi. p. 588.

1765. *Ranula* (*Ranula*, Lat.; *Froschgeschwülste*, Germ.; *Grenouillette*, Fr.) is a tumour beneath the tongue, sometimes soft and fluctuating, sometimes hard and firm, at first attended with little inconvenience, but in proportion as it enlarges, it interferes with chewing, and especially with speech. Should the swelling attain a very considerable size, it occupies the greater part of the mouth, thrusts the tongue upwards and backwards, occasionally also the front teeth outwards, and at the same time forms a swelling beneath the jaw. In this state the symptoms just described are very marked, the swelling itself becomes painful, and may inflame and suppurate. *Ranula* is sometimes developed not towards the mouth, but downwards, forming beneath the jaw and on the front and sides of the neck a very considerable swelling, which may be easily mistaken for an abscess.

[The elder CLINE used to mention in his Lectures that he was one morning alarmed by the noise of a person breathing with great difficulty in the next room to his consulting room, and on hastening in he found the man stretched on a chair, and almost suffocated. On being inquired of as to what was the matter, he pointed to his mouth; upon

---

(*a*) Surgical Anatomy of the Head and Neck, p. 415.

looking into which, Cline observed a large *ranula* thrusting back the tongue, which he instantly punctured with a lancet, and relieved the patient from the threatening suffocation.—J. F. S.]

1766. Passing over Paré's opinion of the nature of *ranula*, that it consisted of a cold, moist, clammy, matter, which proceeded from the brain to the tongue, two different views have been taken of it. *First*, It has been considered as an encysted swelling by Fabr. ab Aquapendente, Dionis, Heister, Meckel, in part, von Winter, Syme, and others. *Secondly*, As a stoppage or closure of the Whartonian duct, from which results the retention of the spittle of the submaxillary gland and the distension of the walls of the duct in consequence of the spittle collected in it; an opinion first started by Munichs (*a*), afterwards more especially declared by Louis, and up to the present time held by most writers. This opinion rests specially upon the state of the fluid contained in the swelling, which, similar to white of egg in colour and consistence, by long continuance in the swelling, becomes viscid, dusky, and frequently mixed with stony concretions (1); and upon the possibility, in many instances, by opening the obstructed Whartonian duct with a probe, to discharge the fluid and effect the cure. Reisinger, who frequently found, by examination with a delicate probe, that the Whartonian duct was still pervious, supposes, on the contrary, that the thickening of the spittle was not merely the consequence of it being retained, and that this was always in proportion to the time the swelling had existed, but that unnaturally secreted spittle perhaps accompanied with atony of the duct, caused the development of *ranula*, and that it was not merely formed by the distended Whartonian duct, but that not unfrequently the distended Whartonian duct burst, and the secreted fluid poured out, and was contained in a sac of cellular tissue, not unlike a cystic tumour; in which way the various forms of *ranula*, as well as the often occurring transparency of the Whartonian duct could be accounted for. This opinion has also been more recently put forth by Hennemann (*b*). Kyll endeavoured to deny that *ranula* depends on distension of the duct; inasmuch as it is imposible, that so small and thin a duct could bear so great distension as is observed in large swellings of this kind; that the fluid contained is not at all similar to spittle, but of the consistence of fat oil, brownish, like yellow olive oil, clammy, clear, and transparent; and according to the statement of the patient after the operation, tasteless, and that these conditions are really from the first, and not as Louis supposes, similar to white of egg. When swelling has existed a longer time the submaxillary glands swell, inflame, the and harden, by which their functions are destroyed. *Lastly*, If the spittle continue to flow, as after Dupuytren's mode of operating, the disease diminishes, at least it never increases, which, however, is not always the case. Upon these grounds, Kyll holds to the old opinion; according to him, the swelling has a sac which is probably an hydatid.

[(1) The elder Cline himself had a stony concretion in one of the submaxillary ducts, which was readily removed by a slight cut through the membranes covering it. I am not aware, however, that it was accompanied with any degree of *ranula*.—J. F. S.]

1767. As unfortunately up to the present time pathologico-anatomical observations upon the seat of *ranula* are entirely wanting, it is impossible to give a very decided judgment upon these different opinions, and still

---

(*a*) Praktyke der Heilkunde, p. 141.

(*b*) Beiträge Meklenburg. Aerzte zur Med. und Chirurg., vol. i.

more as several swellings beneath the tongue are known, to which the term *ranula* has been applied, which have nothing in common with it but their seat beneath the tongue. In the entire absence of anatomical observations on the nature of this disease, chemical examination of the fluid can alone be useful in more satisfactorily deciding whether it be spittle or not. I have found this fluid, both in recent and long-continued *ranula*, pale yellow, or brownish yellow, clear, thickly fluid, like white of egg, very fibrous, so that it could not be poured in drops, but hangs together like *mucus*. Its chemical examination showed no resemblance to spittle; it consisted principally of albumen. If, therefore, it be not admitted that the fluid which the submaxillary and sublingual glands secrete, differ from the spittle of the parotid gland in its composition; or if, when *ranula* exists, there be not an accompanying qualitative change in the secretion of these glands, then manifestly *ranula* must be considered as the collection of a peculiar fluid external to the Whartonian duct, beneath the mucous membrane of the mouth, or in a proper sac (mucous bag) which latter opinion I consider most likely, and therefore *ranula* must be ranked with dropsy of mucous bags.

According to the chemical examination of the fluid from a *ranula* of a boy of twelve years old, which my respected friend and colleague L. GMELIN has published, it consists of water 94·6, of soluble albumen with a very small quantity of stearine, osmazome, salivary matter (?), and carbonate, nitrate and acetate of potash, 5·4, in 100 parts. Hence the fluid has no resemblance to spittle, as it wants the sulpho-cyanite of potash, and almost the entire salivary matter; on the other hand, it contains a large proportion of albumen, which does not exist in healthy spittle. Opposed to this is the examination by DR. L. POSSELT, of a stone weighing 0·623 of a grain, which I removed from the Whartonian duct, from which it appears that in 100 parts were contained 7·8 of matter soluble in water, which showed the reaction of salivary matter; 13·3 of matter insoluble in water (salivary mucus); 68·87 of phosphate of lime, and 9·93 of carbonate of lime. POGGIALE found a stone from the Whartonian duct to consist of 94§ of neutral carbonate of lime, 4 per cent. of animal matter, and 2 per cent. of water.

According to FLEISCHMANN, there are a pair of mucous bags beneath the tongue, upon the *m. geneo-glossi*, where they enter the tongue, a little distant from its front edge, in the *frænulum linguæ*, and behind the opening of BARTHOLIN's duct. They are some lines in length, very distinct, and of unequal size on the two sides, the right being generally larger than the left. In one instance it was divided on the right side by a partition into two parts.

When a salivary stone forms in WHARTON's duct, inflammation and suppuration must arise in its gradual enlargement, by which the stone will be spontaneously thrown out, as I have twice seen; but never, even when the duct is completely closed by the stone, is there any condition similar to *ranula*. There is inflammation and swelling of the glands, which if the abscess be discharged by bursting or cutting soon subsides, only a hardness in the surrounding cellular tissue remains for some time.

1768. According to the difference of opinion as the nature of *ranula* is the ætiology different. An altered condition of the spittle has been assumed by which it is disposed to the deposition of stony concretions, or simple thickening of the spittle, and thereby stoppage of the Whartonian duct is set up, or union of the duct by inflammation and the like. In no case have I been able to ascertain any decided causal condition. *Ranula* is not unfrequently observed in newly-born children, and occurs more frequently in early than in later years.

1769. The *treatment* of *ranula* consists either in opening the swelling and discharging its fluid, with which also it must be sought to prevent the complete closure of this opening, so that the ever-collecting fluid may have a continual escape; or in putting a stop to the secretion by exciting a sufficiently smart inflammation, by destruction of the swelling with caustic, or by its removal with the knife. With these several objects various modes of treatment have been proposed. *First.* Opening the swelling with the actual cautery, (Paré,) or with caustic, in persons who fear the knife with butyr of antimony (Zang.) *Second.* Puncture or cutting through its whole length (Louis.) *Third.* Cutting into the swelling and filling it with caustic and irritating materials, honey of roses with sulphuric acid, (Heister, Dionis,) lunar caustic, (Camper,) muriatic acid, (Acrel,) stuffing with lint (Callisen, Schreger.) *Fourth.* Partially cutting away the external wall, (Boyer,) with cauterization of the hinder wall, (Sabatier, Vogel, Wilmer, Chopart, Desault, and others.) *Fifth.* Introduction of a seton (van der Haar and others,) *Sixth.* Introduction of a leaden thread, or of a bundle of lint (Louis, Sabatier.) *Seventh.* Extirpation of the whole sac (Marchetti, Richter, and others.) *Eighth.* Opening the swelling and in healing a little cylinder of two flat small silver, gold, or platina plates, or a similar instrument of elastic gum. (Henning.)

Richter (*a*) recommends, in the *ranula* of children, cauterization with lunar caustic. After a clean good wound has been produced by the first touching the whole surface, the caustic is to be repeated as often as the wound diminishes. This is never required more than ten times.

When the *ranula* is not large and old, and its membranes are thin, the opening of the salivary duct sometimes appears like an aphthous spot, and is only closed with viscid matter or with a stony concretion; in such cases the duct should, according to Louis, Chopart, and Desault (*b*), be again rendered pervious by introducing a probe, and endeavouring to discharge the collected fluid, with which object the passage of the canal must be endeavoured to be kept open, by introducing a leaden thread, which must from time to time be withdrawn to allow the escape of the spittle. All writers agree that this treatment is rarely suitable in its operation, as has been already observed in speaking of the nature of *ranula*, and as in many cases the salivary duct is found pervious, it is highly probable that a change in the condition of the swelling will take place without it.

1770. Of the several modes of treatment, that proposed by Dupuytren is the most simple and certain. A small cut, or a puncture with a lancet is made in the swelling, and after the fluid has been emptied, a silver, gold, or, best of all, a platina cylinder, three inches long, an inch and a half thick, composed of two little elliptical plates, externally convex, and internally somewhat concave, and then the edges may be fixed about the cylinder. My own practice confirms this mode of treatment; I have in every case succeeded in effecting a permanent cure; the inner cylinder produced no inconvenience; and when after some time it was displaced and thrown out, the edge of the inner plate having produced union, and there was no return of the disease. Others have not had success by this method (von Graefe, Kyll.) And if the swelling should afterwards return, the removal of its front wall is most efficient, for which purpose it must be lifted up with forceps, and cut off with Cooper's scissors (*c*).

Reisinger's modification of Dupuytren's cylinder, which he provides with an aperture to allow the constant escape of the fluid, I have found without objection.

[On the whole, I think the best method of treating *ranula* is by hooking up with a tenaculum a portion of its wall, and cutting it out with a pair of scissors; which done, the edge of the wound should be found and freely cauterized with lunar caustic. But it is often necessary to repeat this operation two or three times before a permanent opening can be established. I have, in a few instances, passed a needle and thread through, and including a quarter of an inch of the wall of the swelling in the thread, tied and allowed it to ulcerate out. The success of this mode of treatment is, however, less than that of the former.—J. F. S.]

Sebastian, A. A., Dissert. de Hydrope vesiculæ fellis. Heidelb., 1827.

1771. The already mentioned (*par.* 912) overfilling and distension of the gall bladder when the outflow of the bile by the *ductus choledochus* is prevented, always occurs gradually. The patient, having previously lost his appetite, feels, for a longer or shorter time, a dull pain under the ribs on the right side, which often extends to the region of the stomach and loins. Afterwards there frequently occur, with previously lost appetite, disturbed digestion, costiveness, pain in the right hypochondrion, and more or less severe jaundice, symptoms of colic, the seat of which is, especially opposite the points of the ninth rib, accompanied with frequent vomiting, febrile and other symptoms. If, under these circumstances, the painful part of the right hypochondrion be examined, a more or less distinct round swelling is observed, projecting a little below the front edge of the liver, confused with it above, and more or less easily felt in different positions of the body. The swelling, sometimes of itself, at other times at the very moment when pressed, diminishes and is less tense, whereupon all the symptoms diminish and bilious stools follow. If the distension of the bladder be considerable, and have existed long, the swelling loses its mobility, becomes united to the *peritonæum*, and appears equally attached to the wall of the belly and to the liver.

[In the Museum at St. Thomas's is a gall bladder equal in size to the urinary bladder of an ox, which was taken from a female patient who had been under the care of Cheston of Gloucester. She had had a projection at the pit of the stomach for a few years, which, as it increased, caused her much pain, and was presumed to be an abscess of the liver. It was punctured and a considerable quantity of bile flowed out. The wound was closed, but she died a few days after (*a*).—J. F. S.]

1772. It appears that in this disease the flow of bile into the intestinal canal is most commonly not entirely prevented, and the patient has daily natural coloured motions. The disease may terminate in biliary fistula, in which case the gall bladder having adhered to the *peritonæum*, the bile collected in it makes its way out externally. The gall bladder may also grow to the *colon* or to any other intestine, and empty itself into it; or no union with the *peritonæum* having taken place, it may burst, and a fatal effusion of bile into the cavity of the belly may ensue.

[Sometimes when the *ductus choledochus* is obstructed, the gall bladder becomes adherent to the *duodenum*, ulceration takes place, and by this new opening the bile is, and continues to be discharged, and the functions of the gall bladder ceasing, it diminishes to the size of an acorn, as in a preparation in St. Thomas's Museum.—J. F. S.]

1773. As to the *treatment* of this disease, at first it is merely confined to the use of those remedies which soothe or remove the irritable or inflammatory condition. At the same time it must be attempted, by rubbing, stroking, and pressing the swelling, to empty part of its contents into the *duodenum*, and to apply discutient remedies. As long as it is uncertain that there is considerable union of the gall bladder with the *peritonæum* (which may indeed be presumed, although it cannot be asserted

---

(*a*) MS. Lectures.

with perfect surety, if the patient have had frequent symptoms of inflammation and the swelling is no longer movable, as also by a slight adhesion the latter may be effected) we must not dare to undertake the evacuation by opening the gall bladder, as fatal escape of the bile is to be dreaded. For this reason it appears not advisable to open the swelling previous to the inflammation of the wall of the belly, and even of the external coverings being distinctly ascertained, that the bile may make its way out externally, in which case the adhesion is always to a proper extent (*a*).

1774. Opening the gall bladder is best managed by making a cut into the skin an inch and a half long upon the swelling, and then smaller cuts through the muscles down to the *peritonæum* ; then with the forefinger of the left hand it must be cautiously ascertained if the gall bladder adhere, and at the most fluctuating part the bistoury or lancet should be thrust through the *peritonæum* and the wall of the gall bladder. If the adhesion between the gall bladder and *peritonæum* be not fully made out, then, after the *peritonæum* has been laid bare as just mentioned, a trocar is to be thrust into the most fluctuating part and the tube left in till the gall bladder and *peritonæum* have united together, or caustic should be applied to the *peritonæum* to produce this union (*b*).

1775. When the gall bladder has been emptied the opening must be gently filled with lint, the inflammatory symptoms excited must be treated with proper remedies, and in other respects it must be treated as has been already mentioned in biliary fistula (*par.* 913.)

1776. *Retention of Urine* (*Retentio Urinæ*, *Ischŭria*, Lat.; *Urinver-*

(*a*) Delpech; Précis Elémentaire, vol. ii. p. 272.

(*b*) Richter; Anfangsgründe, vol. v. p. 125-27.

haltung, Germ.; *Retention d'Urine*, Fr.) designates those diseased conditions in which the urine is retained by any obstacle in the canals destined for its discharge. This obstruction may be in the kidneys, in the bladder, or in the *urethra*, and hence is named either *Ischuria renalis, ureterica, vesicalis, urethralis.* The discharge of the urine is thereby either completely stopped, or it may be voided with difficulty (*Dysuria*) or only by drops (*Stranguria.*)

Retention of urine from growing together of the lips of the *urethra* has been already treated of (*par.* 1702.)

That state of disease in which, on account of local disturbance in the kidneys or by a general disease, *no urine is secreted*, (*Anuria, Suppressio Urinæ,*) must be distinguished from retention of urine (*a*).

1777. Retention of urine in the urinary passages and in the kidneys may be produced by foreign bodies which fill their cavities, as stones, hydatids, lumps of blood, pus, thick mucus, worms, or by inflammation, chronic swelling, and spasm of these passages, or by swellings which compress the bladder. The obstruction which prevents the passage of the urine through the ureters is rarely on both sides, therefore complete retention of urine is rare; the flow of urine may be completely or incompletely prevented.

1778. All the symptoms which manifest *retention of urine in the ureters* are doubtful. The patient feels more or less violent urging, stabbing pain, extending from the region of the kidney downwards, and increased on motion. Although there may be a smaller discharge of urine, yet are the signs deficient which show a collection of urine in the bladder. But if the patient have previously voided some little stones with the urine, if with previous pain in the kidneys a stabbing pain seem to strike downwards, and there be a sense of weight and tension at one particular spot, it may be presumed, with probability, that the ureter is stopped by a stone. The distension of the ureter above the obstruction becomes gradually greater, though externally no swelling be observed, which, however, is contradicted by ALLAN's (*b*) case (1).

At last the urine collects in such quantity that the ureter increases to double and triple its size. If the stoppage be only at one part, the ailment may continue longer without particular inconvenience; under which circumstances, by the vicarious activity of the other kidney, the ordinary quantity of urine is passed. The dangers which may be specially produced by *Ischuria ureterica*, are complete suppression of the urinary secretion, by which the following general symptoms may be caused: inflammation, suppression, and bursting of the ureters and kidneys; in which case extravasation of urine into the cellular tissue and urinary *fistulæ* follow, or if the urine be poured into the cavity of the belly, fatal inflammation.

(1) The patient suffered early from gravel, and treatment was employed proper for symptoms of stoppage of the ureter by stone, which passed off in four days. A swelling then arose on the left hip, which daily increased, whilst the quantity of urine daily diminished. Three weeks from the commencement of the disease the skin and muscles were cut through above the crest of the hip-bone, and the transversal *fascia* pierced with a trocar, which was thrust into the cavity beneath, from which seven pints of urine escaped. The symptoms diminished; no tube was left in; the symptoms of irritation returned, and after a week, a tube having been again introduced, six pints of urine and two of pus were evacuated. The disease subsided, and recurred from time to

---

(*a*) ABERCROMBIE, J.; in Edinb. Med. and Surg. Journ., vol. xvii. p. 210. 1821.

time. The patient died five months and eleven days after the operation, during which time the urinary fistula remained. Death was caused by gradual wasting. On dissection, the kidney was found expanded into a cellular sac, the mucous membrane of the ureter thickened, and completely closed below with coagulable lymph (*b*).

1779. The *treatment* of *Ischuria ureterica*, when accompanied with violent pain and inflammatory symptoms, consists only in the employment of antiphlogistic remedies, blood-letting, soothing clysters, bathing, stoups, and the like. In the contrary condition, shaking motions, as riding, and even vomiting may be successfully employed, in order to favour the descent of the stone in the ureter.

1780. When the *urine is retained in the bladder*, various symptoms occur according to the degree and duration of the collection. The patient feels a constant urging to void his urine, but is unable to do so; there is weight and tension at the lower part of the belly, and in the *perinæum*; a swelling rises above the *pubes*, elastic and at times fluctuating, ascends oftentimes up to the navel, and even still higher, generally in the middle of the belly, but sometimes more to one side than the other. As the bladder enlarges, especially from above downwards, so it thrusts down its base, forcing it against the *perinæum*, presses upon the *vagina* and in men upon the *rectum*, where on examination with the finger introduced into the gut, it is felt as a compressible elastic swelling. Sometimes the bladder is but little distended, on account of the peculiar rigidity of its coats. In fat persons the swelling is not so distinctly felt as in thin ones.

An important symptom which is rarely wanting, and which may be perceived even in very stout persons, is the dull sound perceived on percussion from the sword-like cartilage down along the white line, and from the iliac spine of one side to that of the other, in the region of the bladder, by which, as well as by the shriller abdominal sound in the neighbourhood of the bladder, the extent of that organ can be ascertained. Another important pathological sign is the fluctuation of the fluid in the bladder, which is perceived when, with one finger in the *rectum* or *vagina*, and the other hand placed over the region of the bladder, it can be produced and felt by the alternate pressure of one or other (PIGNÉ.)

1781. If the urine be not passed in the usual way, the distension of the bladder becomes greater, and the result of the disease varies. The bladder may burst by partial gangrenous destruction (1), and the urine be poured forth into the neighbouring cellular tissue, in which case either urinary *fistulæ* are formed, or death ensues as the consequence of gangrenous inflammation of the bowels. The bladder may be violently inflamed, and the inflammation spread over the abdominal intestines. Sometimes, when the bladder has attained its greatest distension, the ureters are also considerably distended up to the kidneys, which on account of the oblique entrance of those canals into the bladder, has been doubted by some persons. From the decomposition of the urine, and its reaction upon the whole organism, severe fever arises, with speedy sinking of the powers, extremely quick pulse, dry tongue, *coma* and *delirium*; the perspiration of the whole body has an urinous smell; all the excretions are altered; often there is watery vomiting with an urinous smell, and the patient soon dies. Sometimes the *urachus* opens, and the urine flows out through the navel (2).

[(1) Bursting of the bladder from retention of urine either without or with gangrene is of very rare occurrence; I have never seen nor had personal knowledge of such a

---

(*b*) London Medical Gazette, vol. xix. p 838. 1837.

case. Nor, as far as I am aware, is gangrene even of the bladder often met with. CHESTON indeed mentions (*a*) an instance, which however I think seems very doubtful. A woman thirty-five years of age, and four months gone with child, had suppression of urine, for which a catheter was passed, and five pints of water drawn off. Seven or eight days after she again had retention, but then only half a pint of water could be withdrawn by the instrument; after this, however, water continued to pass. On the fourteenth or fifteenth day from the first attack she died, the bladder having risen up to the navel. On examination, it was found to contain a quart of fœtid, thick, purulent urine, and the *fundus* of the bladder is stated to have been completely sphacelated. The walls of the bladder had doubled by the pressure of the womb, so as to form two cavities, and this fold had prevented the entrance of the catheter.

(2) The opening of the *urachus*, I think, must be admitted with very considerable doubt. I have on one occasion, however, seen in a healthy woman a very small oozing of clear fluid entirely free from smell or acridity from the navel, which I thought might have been from the *urachus*. It had existed for a considerable time. Astringents were used for some time without advantage, and she ceased coming to me.—J. F. S.]

1782. If a retention of urine have been slowly produced, so that for a long time previous, only part of the urine has been voided, whilst the bladder itself still remained full, the symptoms are less active. From the urine collected in the bladder, which becomes decomposed, a slow inflammation is produced, which specially attacks the mucous membrane, and alters its secretion. The general health is disturbed, the digestion suffers, the countenance pales, the muscles become flabby, the patient suffers from fever, and the like. The walls of the bladder often become much thickened, and frequently folds, and all the deepenings are produced by the separation of the muscular fibres (1).

(1) These sac-like deepenings are the first step of the spontaneous perforation of the bladder, which MERCIER (*b*) has well described, and which has been considered to be caused by the use of the sound. The mucous membrane of the bladder pushes into these deepenings, and is sometimes in immediate contact with the *peritonæum*; sometimes separated from it by a peculiar thick layer of cellular tissue. These deepenings occur specially on the sides, and on the under part of the hind wall of the bladder, above the openings of the ureters. After a certain time the mucous membrane often ulcerates at the bottom of these sacs, and is followed by a pouring forth of the urine; the mucous membrane may even be torn in retention of urine, and in the violent efforts to discharge it, which cause these cell-like deepenings, after or even without previous ulcerative inflammation (2). As the bottom of these sacs have not contractility, which their opening, surrounded by muscular fibres, have, the urine contained in them, is with difficulty renewed; it collects, decomposes, and produces inflammation. Sometimes stones form in them, which gradually enlarge, and distend the bottom of the sac, without enlarging its opening, and thus encysted stones are formed, which may also excite inflammation, and cause perforation. The suppuration which results from such perforation, may spread into the cellular tissue beneath the *peritonæum*, and there form one or more abscesses, which open into the *peritonæum*, either without previous adhesion, in consequence of which death speedily follows; or after the suppuration has been bounded by adhesion, in which case fatal symptoms less frequently follow. Sometimes the abscess opens into an intestine, sometimes in the wall of the belly, into the flank, and so on, and cause death only consecutively. Under these circumstances also urinary *fistulæ* may be formed (PIGNÉ.)

[(2) The bursting of these deepenings or sacs is certainly very rare.—J. F. S.]

1783. The causes of retention of urine in the bladder may be, *first*, palsy of the bladder; *secondly*, inflammation; *thirdly*, spasm; and *fourthly*, stoppage of the urine depending on foreign bodies introduced into the *urethra* or bladder, or on stones, coagulated blood, and so on, on swelling and hardening of the prostate gland, on growths in the bladder, on

---

(*a*) Pathological Inquiries and Observations in Surgery. Gloucester, 1766. 4to.

(*b*) Gazette Médicale, vol. iii. p 312, 1835.

pressure of the impregnated or unimpregnated womb, on swellings or hardened intestines, or on strictures.

1784. *Paralytic Retention of Urine* (*Ischuria paralytica*) in general comes on slowly, the urine is no longer discharged with the usual power, the patient soon feels the need of voiding it again, which he can only effect with the greatest exertion. This difficulty gradually increases, the urine at last flows off involuntarily, and the patient can by his efforts but little or not at all increase the flow, which at last stops completely. The distended bladder forms the already mentioned (*par.* 1780) swelling above the *pubes*, which is nearly painless, and sometimes in such degree that it may be mistaken for pregnancy or dropsy, which may be the more possible as the patient occasionally retains the power of voiding his urine by violent efforts, often even in a quantity equal to the drink taken in the day, without, however, emptying the distended bladder. If the filled bladder be somewhat firmly pressed, a few drops of urine will escape through the *urethra*.

Sometimes paralytic retention arises quickly under severe symptoms of a spasmodic and inflammatory affection of the neck of the bladder, when, if speedy assistance be not afforded, considerable distension of the bladder, and palsy of its walls are produced. In the later course of the disease, there are accompanying it a flow of *mucus* from the bladder, thickening of its walls, swelling of the prostate gland, and the like. This kind of paralytic retention of urine happens most commonly in old persons who have been dissolute in various ways, have suffered from gout and rheumatism; and usually the gout or rheumatism is the proximate cause.

1785. When the bladder in this retention of urine has become very much distended, the pressure of the abdominal muscles and bowels prevents its further distension; some urine always dribbles, and bursting of the bladder does not take place. But inflammatory symptoms, and more or less severe fever may accompany it. The flow of urine is then completely stopped, and the bladder may be distended to such extent that it may become grangenous and tear; this, however, is a rare termination.

OESTERLEN (*a*) divides paralytic retention into *Ischuria paralytica partialis vesicæ*, in which the powers of the bladder and abdominal muscles are very weak; and *Ischuria parylytica universæ vesicæ*, in which there is accompanying palsy of the bladder, and the *sphincter* muscle of that organ.

1786. This form of retention of urine is peculiar to old people, and depends on the loss of contractile power in the bladder, and on the generally diminishing muscular activity in advanced age. It may be the result of previous debilitating causes, debauched life, venereal disease, frequent onanism. The bad habit of holding their water very long frequently produces it in persons who lead a sedentary life, who work hard and frequently allow the disposition to make water to pass by without attending to it. It may also result from concussion and palsy of the lower part of the spinal marrow and sacral nerves, or from organic disease of the spinal marow: it frequently occurs in nervous fevers.

1787. The *prognosis* of this disease is guided by its degree and duration, by the age of the patient and by its cause. It is most easily cured in young people; the older the patient and his disease are, the less hope is there of cure. If the disease be caused by affections of the spinal marrow and sacral nerves, the *prognosis* must be directed by them.

(*a*) Heidelb. klinisch. Annalen, vol. viii. p. 421.

1788. The *treatment* of paralytic retention consists in emptying the bladder of its urine, and in restoring its contractile power. The remedies which answer to the latter indication are useless without attention to the former.

1789. Emptying the bladder by means of the catheter, must be performed so frequently, that all distension from the collecting of the urine must be prevented. The catheter may be either introduced afresh as often as necessary, or an elastic catheter may be left in, which in all cases where the patient is not under immediate observation, is the most fitting, as the urine often collects again with great quickness, and therefore the bladder again becomes greatly distended. The introduction of the catheter is in these cases always unattended with difficulty, and generally in a short time the patient may learn himself to pass it. If the bladder be weak, the urine sometimes only flows through the catheter, when pressure is made on the belly. This indisposition of the urine to pass by the catheter, may lead to the mistake that the instrument is not in the bladder (*a*). The catheter must be continued till the urine pass through it, and between it and the *urethra*, in a strong unbroken stream; and if even the patient should void his urine without the catheter, it should be frequently ascertained by introducing it, that no urine be retained in the bladder.

1790. The remedies which answer the second indication are, cold bathing of the pubic region and *perinæum;* cold applications, cold injections into the *rectum;* rubbing volatile salves on the *perinæum*, and on the region of the bladder. Internally should be given *arnica*, *oleum animale Dippelii*, *cantharides* to the amount of a grain daily with camphor and gum-arabic, tincture of *cantharides* up to fifteen or twenty drops, with almond milk. And in addition to these general strengthening baths, galvanism, electricity, and blisters upon the *sacrum*. When the patient can again himself discharge his urine, he must not dare to allow the least disposition to void it to pass unsatisfied.

1791. In the quickly occurring paralytic retention, where gout or rheumatism are in play, warm sulphur baths, fomentations of aromatic herbs with wine and vinegar, rubbing in oil of juniper, particularly on the inside of the thighs; cupping and easily digestible diet are to be used. If violent inflammatory symptoms be present, leeches are to be applied to the *perinæum*. The introduction of the catheter, necessary as it be, is generally difficult on account of the contraction of the neck of the bladder.

1792. If paralytic retention have existed for some time, and be accompanied with an inflammatory condition, it must, according to circumstances, be treated antiphlogistically with blood-letting, clysters, diluting, slightly astringent drinks, as alum milk, and the like. If the disease be incurable, as frequently it is in very old persons, and if it have long existed, the patient should always use a catheter for emptying his bladder.

A somewhat contrary condition to that of palsy of the bladder is that in which, consequent on some irritation, or bad habit, the urine is voided too quickly, and thus the capacity of the bladder gradually so diminished, that only the smallest quantity of urine can be made, and therefore painful urging on the collection of the smallest quantity of urine becomes habitual. The gradual origin of this condition may be inferred from its history, and if on examination with the catheter, no stricture in the *urethra* be found, no foreign body in the bladder, and the catheter do not pass into the cavity of the bladder.

The *treatment* of this ailment must consist in the gradual extension of the walls of

---

(*a*) Oesterlen; above cited, p. 420.

the bladder to their natural condition, which must be done by voluntarily retaining the urine, or if this be impossible, by introducing a catheter morning and night for a long while, by which the intervals of relieving the bladder may be gradually lengthened (*a*). The over-sensibility of the bladder is thereby checked by compelling it to bear a greater degree of irritation, and by the same means also the contractile power of its *sphincter* may be increased. In most cases this great sensibility of the bladder is connected (when it does not depend on local disease in the urinary passages) with disturbance of the digestive organs and irregular living, and requires gently purgative and afterwards tonic remedies, lukewarm bathing or washing the *perinæum* with lukewarm water, clysters with opium, purgatives, and strictly regulated diet.

1793. *Retention of Urine, depending on inflammation, (Ischuria inflammatoria,)* commences with the most violent and dangerous symptoms. Besides great urging, the patient feels a deep-seated pain in the bladder and neighbouring parts. There is accompanying fever, the distended region of the bladder smarts when touched, and is frequently reddened. The inflammation spreads over the other bowels; eructations and vomiting occur, and if they continue beyond the sixth day, the patient's life is in extreme danger, and death is almost unavoidable. Sometimes the inflammation takes a more insidious course, and puriform secretion with thickening of the bladder occur.

1794. The inflammation in this retention may be seated in the whole canal of the *urethra*, in the neck of the bladder, in the prostate gland, and even in the bladder itself.

Its *causes* are, external violence, which attacks the *perinæum* and region of the bladder, stones in the bladder, extension of the irritation of the *rectum* in hæmorrhoidal affections to the bladder, rectal *fistulæ*, and the like; a high degree of inflammation in *gonorrhœa*, suppression of the usual discharges, suppressed gout, repressed eruptions on the skin, and catching cold.

1795. Antiphlogistic remedies must be employed in inflammatory retention of urine, with reference to the cause which has produced it. Blood must be taken away and leeches applied to the *perinæum;* mucilaginous drinks taken, though in as small quantity as possible, in order not to increase the filling of the bladder. As in inflammatory retention, spasmodic contraction of the neck of the bladder is always present, warm anodyne applications must be made to the *pubes* and *perinæum*, warm vapour of camomile to the *perinæum*, rubbing in volatile ointments, clysters with opium, and the like employed. Tobacco clysters are much relied on. Blisters must not be applied; calomel and opium internally are specially effective.

1796. In severe gonorrhæal inflammation soothing applications are also to be made over the whole *penis*, the patient laid horizontally, and the testicles supported with a suspender. In hæmorrhoidal affections leeches are applied to the *rectum*, and internally, cream of tartar and sulphur given.

1797. Although emptying of the urine be necessary, as by its irritation it causes the inflammation, it must not be used till the remedies already recommended have been employed. The introduction of the catheter is here always painful and difficult; an elastic one is best used, and its point should be passed far into the bladder, so that its walls should not be irritated. If the catheter can in no way be introduced and mortification of

---

(*a*) VON WINTER; über die Harnbeschwerden von verminderter capacität der Harnblase; in GRAEFE und VON WALTHER's Journal, vol. i. p. 309. —HYSLOP; in Med.-Chir. Trans., vol. vi. p. 108. —BINGHAM; above cited, p. 234.

the bladder be dreaded, puncturing the bladder must be performed without delay.

1798. In *Spasmodic Retention of Urine* (*Ischuria Spasmodica*) the neck of the bladder, and perhaps also the *urethra*, are narrowed at different parts, and accompanied with spasmodic contraction of the perinæal muscles. It occurs specially in sensitive persons, in hypochondriacs, in hæmorrhoidal affections, in which there is often at the same time present spasmodic contraction of the *m. sphincter ani*, from catching cold, inordinate drinking, worms, holding the water too long, and the like. This retention is always peculiar in sometimes subsiding and again recurring; it therefore has not the signs of inflammatory retention, at least in general they are not present, though they may at a later period accompany it.

1799. In this form of retention antispasmodic *remedies* are usually employed, warm applications of camomile, *hyoscyamus*, and the like, to the *perinæum* and region of the bladder; rubbing in volatile ointments, with opium or *ol. hyoscyami;* clysters of camomile, *asafœtida* and opium, tobacco clysters (*a*), lukewarm camomile hip-baths. Internally should be given Dover's powder, or opium, with mucilaginous remedies, *pollen lycopodii*. According to its various causes, should be employed, in hæmorrhoids, sulphur, with cream of tartar; in colds, diaphoretic remedies, especially camphor in proper doses; in worms, anthelmintics; and according to the fancy, unfermented drinks, calcined *magnesia*, with aromatics; and the *glans penis* to be put in cold water.

1800. If by this treatment the urine do not flow, a catheter must be introduced, which always discovers a considerable obstacle at the neck of the bladder, sometimes even in the passage of the instrument in the *urethra*. If inflammatory accompany the spasmodic symptoms, the antiphlogistic must be added to the antispasmodic remedies. If the retention of urine have occurred from having voluntarily retained it for a long time, in which case the symptoms are always more severe on account of its greater quantity, the treatment must immediately commence with the introduction of the catheter.

1801. The *retention of urine which depends on stoppage of the urethra* may be produced by stones in the bladder, when they lie upon the inner aperture of that canal, or if being small, they have squeezed into it (1); by coagulated blood (2), or thickened mucus; by worms which pass out with the urine (3); by foreign bodies which have been passed from without into the *urethra* (4). In all these cases the *urethra* is either completely closed by the foreign body, or in consequence of the irritation and spasmodic contraction which they have excited.

[(1) Stones, if small enough to escape from the bladder, may, according to their size, either pass through and be voided by the *urethra*, or they may be fixed in either of its narrower parts. I have known them lodge in the membranous part, and require removal by cutting through the *perinæum;* but more commonly they get jammed within an inch of the lips of the *urethra*, of which I have seen many instances.

In the Museum at the College of Surgeons, there is a very remarkable instance of a case which occurred to John Hunter, in which a narrow stricture in the membranous part of the *urethra* was blocked up by a very small stone, hardly more than a line in diameter; it is figured, in his work, *On the Venereal Disease*, (pl. iv.) and the short notice attacked to it is, that the man "died of a mortification of the bladder, in consequence of a stricture and stone in the *urethra*." This preparation is interesting, as the stated cause of Hunter's beginning to use caustic bougies, for he adds, "a canula is

---

(*a*) Earle, Henry, On the use of Nicotiana in Retention of Urine; in Medico-Chirurg. Trans., vol. vi. p. 82. 1815.

introduced from the *glans* down to the stricture, showing the practicability of destroying it with caustic." In the same collection, there is also another instance of a stone in the *urethra* behind a stricture, in a boy of four years old, to which he refers, (p. 124,) in the same work.

(2) HOWSHIP (*a*) gives a good example of blood filling the bladder, in an elderly man, who was attacked with what was at first supposed to be a retention of urine, and a catheter having been repeatedly passed without any urine escaping, it was thought not to have entered the bladder. He died on the following day, and on *examination*, the bladder was found entirely filled with a very large coagulum. In another case, he mentions the bladder being nearly filled with blood, and containing a stone in the centre of the clot.

When blood is found in the bladder, it is more commonly from fungous growths either from the bladder itself, or from the prostate, of which BRANSBY COOPER (*b*) gives good examples.

The case of MATHIEU's, quoted by SAMUEL COOPER (*c*), appears to me nothing more than an enlarged prostate, which the catheters first used were not of sufficient length to reach beyond, and not retention from a clot in the bladder.

I have known, in two or three instances after the operation for the stone, blood to flow back into the bladder, and there coagulating, prevent for a time the escape of urine, either from the *urethra* or from the wound. Indeed, if for some hours after the operation, urine do not pass from the wound, it may, be presumed something of this kind is going on, and the bladder requires gently washing out, through the wound, with a syringe.

(3) LAWRENCE (*d*) relates a very remarkable instance of an undescribed species of worms voided from the *urethra*, to the amount of from eight hundred to a thousand, by a woman, aged twenty-four years.

He also mentions examples of the *larvæ* of insects having been passed. Of discharges of worms and insect *larvæ*, and portions of the lining membrane of the bladder, which have been mistaken for them, there is no lack in the accounts of various writers.

(4) Foreign bodies, of various kinds, have frequently been purposely introduced into the *urethra*, and escaping from the fingers of the holder, have either lodged in it, or more generally slipped back into the bladder. Bougies, and elastic catheters, and even those of metal, have been thus occasionally circumstanced by accident, the whole of the former being sucked in, as it were, by the bladder; and the latter having been broken, being pushed in by unskilful endeavours to prevent their escape backwards. But tobacco-pipes used as substitutes for bougies, are probably the most common foreign bodies which are met with in the *urethra* or bladder. TYRRELL (*e*) had a case in which the patient broke off three inches of the curve of a silver catheter, which slipped into the bladder. He walked to St. Thomas's, a distance of about twenty-one miles from his residence, without much inconvenience, except that "occasionally in stooping, walking up stairs, or raising himself in bed, he experienced lancinating pain, as if some sharp instrument were penetrating the bladder. * * * On passing a sound, it was found lodged at the *fundus* of the bladder transversely; its extremities being embraced by that *viscus*, so as to be held with some firmness." It was brought lower with a sound, but still remained transverse. TYRRELL "then introduced one of WEISS's instruments for extracting small *calculi*, which was nearly straight, and had a strong spring; by careful examination with which, he discovered that the extremity of the foreign body towards the patient's right side was free, and that the other was covered with a fold of the bladder. After several unsuccessful attempts, he succeeded in seizing the free extremity with the instrument, and by withdrawing it very cautiously, brought the piece of catheter into the *urethra*, when the forceps slipped from it. He immediately introduced his fingers into the *rectum*, for the purpose of compressing the *urethra* between the foreign body and the bladder, so as to prevent any retrograde movement of the former. This being secured, he again introduced the forceps into the *urethra*, and in the first attempt caught the piece of catheter, and drew it out."

I am indebted to my friend CRISP, of Walworth, for the two following highly interesting cases, which were treated by him:—

Case 1. An old sailor had been in the habit of passing the whole length of a tobacco-pipe into his *urethra*, for the relief of stricture, and on one occasion broke off a piece of it, which slipped into his bladder, and for which the usual operation for the stone was performed in Guy's Hospital, and he recovered. This accident, however,

(*d*) Med.-Chir. Trans. vol. ii. p. 382.

(*e*) St. Thomas's Hospital Reports, p. 26.

did not prevent him subsequently recurring to the same mode of treatment, when the pipe again broke, leaving about an inch and a half in the membranous part of the *urethra*. This he attempted to remove, by making a cut with a penknife into the *perinæum*, as he lay before a glass, and succeeded in exposing the pipe, but being unprovided with instruments, and failing, by groping with his finger, to get it, he was obliged to send for my friend, who drew it forwards with a pair of dressing forceps, and readily removed it. The man did well.

Case 2. A man in Walworth workhouse, having made frequent attempts to commit suicide, at length, for the same object, passed a piece of stiff wire, about five or six inches long, into the *urethra*, as far as he could, and afterwards drove it with his fist under the arch of the *pubes* into the *pelvis*. By pressure on the *perinæum*, the extremity of the wire was indistinctly felt. A cut was made into the *urethra* behind the bulb, about an inch and half in length, but the wire end not being seen, the cut was lengthened backwards about half an inch, which exposed the extremity of the wire. Much difficulty was found in seizing the wire, as at each attempt it receded with the soft parts, when the points of the dissecting forceps (which only could be used, on account of want of space) were introduced; but when seized, it was readily withdrawn, and the man recovered.

John Hunter says, that "bougies have been known to be forced out of the bladder along with the water, by the action of that *viscus*, and in several folds. (p. 134.) This is certainly a very rare occurrence, but, by no means, impossible or improbable; for there is a preparation in St. Thomas's Museum, of a large adventitious membrane, four or six inches long, and an inch and a half wide, which was voided by the *urethra*; and it is only necessary for the bougie to be so situated, as to form a sort of plug, against which the urine behind may be driven forwards.—J. F. S.]

1802. If a vesical stone lie against the neck of the bladder, and produce ischury, the same proceeding as in inflammatory ischury, must be had recourse to, and the stone removed from the neck of the bladder, either by placing the patient on his back, with his *pelvis* raised, or by introducing a catheter. Lumps of blood and collections of mucus in the *urethra* are also relieved by passing the catheter. If small stones or other hard bodies stick in the *urethra*, itself, it must be attempted, by employing, at the same time, antiphlogistic and antispasmodic remedies, to squeeze them gradually out of the *urethra*, or with Hunter's or Cooper's forceps to withdraw them, after having carefully enlarged the passage by introducing thick bougies, especially of silkworm gut. If the object be not thus attained, a cut must be made, where the foreign body is situated, and thence it must be removed (1): a catheter is to be left in afterwards, and the edges of the wound tried to be healed with quick union (2).

Retention of urine from small stones, which have got into the mouth of the *urethra*, or into its membranous part, is probably much more frequent, than generally supposed; in which case the *diagnosis* is doubtful, and if the catheter be introduced, the little stone cannot be felt, and the retention on the contrary, is to be considered inflammatory or spasmodic. As symptoms of such *ischuria calculosa* may be to a certain degree considered their occurrence after any mechanical movement, without other previous influence and their cessation after such shaking. For the removal of these little stones, when the introduction of a catheter is not possible, for instance, when there are existing strictures, injections of water, made with some force into the *urethra*, must be employed; together with rubbing and shaking the *perinæum*, but the bladder must not be previously overloaded, or the *urethra* considerably inflamed (*a*).

[(1) If a stone or any other body be near the lips of the *urethra*, it may often be removed with a little dexterity and patience, by curving the eyed end of a probe, and gently insinuating it between the stone and the *urethra*, till the point be got behind it; then using the probe as a lever, it may be gently drawn forwards, and if when the stone reach the orifice of the canal, it will not pass, a small nick with a lancet at that part of the aperture, where it most clings, will soon allow it to come out. If the stone or body be in the membranous part, if the forceps fail in catching hold and pulling it out, a cut must be made directly down upon it. But in doing this it will be necessary to introduce

---

(*a*) Schreger, Chirurgische Versuche, vol. i. p. 187.—Cloquet, I.; in Journ. de Médecine, vol. ii. p. 19. 1818.

the forefinger of the left hand into the *rectum*, so as to fix the stone and prevent it slipping or being pushed back into the bladder, in the attempt to seize it: for should that happen, it will be necessary at once to perform the usual operation for stone.

(2) If the cut be made in the *perinæum*, no catheter should be left in, but the wound allowed to heal, as after the operation for the stone. But if the *urethra* be opened before the *scrotum*, and specially if near to it, a catheter must be left in, to prevent the escape of the urine into the cellular tissue.—J. F. S.]

1803. In *retention from the pressure of the impregnated womb, or other viscera*, the palliative treatment consists in introducing the catheter: in the former case the ischury ceases after delivery; in the latter the hardening of the *viscera* must be got rid of, as well as other swellings which compress the *urethra*. Retention from retroversion of the womb has been already considered (*par.* 1308.)

[I once operated for retention of urine in a case which, after death, was found to depend on a large cyst, containing an acephalous hydatid, which occupied the whole cavity of the *pelvis*, and lying between the bladder and the *rectum*, compressed the former between itself and the *pubes*, and as the bladder filled, it rose high above the brim of the *pelvis*, in consequence of which, even after cutting into the *perinæum*, the pressure was so complete that the urine would not escape, except on the introduction of a very long catheter, which was continually displaced by the contraction of the bladder into the compressed part, into which no urine descended, and was only replaced with the greatest difficulty. The man died on the sixth day of constitutional irritation. Besides this cyst above mentioned, which contained 44 ounces of colourless fluid enclosed in the hydatid, there was another, about the size of a goose's egg, at the lower part of the sigmoid flexure of the *colon*, with thick walls, and an eschar upon it, where it had probably, at some time or other, burst. The bladder was empty between the lower and fore part of the large cyst and the arch of the *pubes*; and between the cyst and the back of the *fundus* of the bladder were two or three small cysts of the size of small nuts, and upon the fore part of the *fundus* another as big as a swan's egg. All the cysts contained each an hydatid, except that on the *rectum*, on which there were several.—J. F. S.]

1804. *Growths in the bladder*, especially about its neck, are causes of ischury, and the diagnosis is always uncertain. Sometimes there is only one growth of much size, sometimes several: some have a thin stem, and others a broad base. The use of the catheter is the only palliative. Such growths when discovered in the operation for the stone, have been torn away with the forceps (*a*).

1805. *Swellings of the prostate gland* may arise in various ways, and the passage of the urine become difficult, or quite impossible. The swelling may depend on inflammation, varicosity of the vessels, hardening, and stone.

1806. *Inflammation of the prostate gland* may be consequence of *gonorrhœa*, of external violence, and the like; in general, it developes itself quickly. The patient has a sense of weight and burning in the *perinæum* and *anus*, a throbbing pain, the seat of which he refers to the neck of the bladder. The pain increases on pressure of the *perinæum*, and specially on going to stool: the patient has difficulty and frequent urging to void his urine: the swelling of the prostate is felt on introducing the finger into the *rectum*. In proportion to the degree of inflammation, occur inflammatory symptoms and so on. If the inflammation do not disperse, it may pass on to suppuration. Under these circumstances, after the inflammatory symptoms have gone over eight days, a throbbing pain is felt, increased fever towards evening, shiverings, and symptoms of retention of urine, which subside a little, and increase afresh. The suppuration rarely appears to be seated in the proper substance of the gland, but rather

---

(*a*) DESAULT; above cited, p. 175.

in its coverings, and in the cellular tissue, connecting the lobes of the gland; frequently several groups of abscesses form, and in this case the patient generally sinks, some abscesses opening within, and others without, the abscesses burrow, and fistulous passages, and wasting suppuration ensue.

[" As the abscess advances, the *perinæum* becomes tender," says **Brodie**, "and there is a perceptible, though slight tumefaction and hardness in some one part of it. The abscess, if left to take its own course, sometimes bursts internally, that is, into the *urethra*; more frequently, it makes its way through the *fascia*, cellular membrane, and muscles of the *perinæum*, and bursts through the external skin." (p. 144.) **Brodie**, however, mentions a fatal instance of abscess in the prostate, in which the patient, about thirty years of age, voided his urine every twenty or thirty minutes, complaining of an aching pain in the loins; but of no pain any where else. The urine deposited a small quantity of yellow puriform sediment. He said that the symptoms had begun two years ago, and that in the commencement of the disease, the urine had been tinged with blood. * * * About a month after his admission into the hospital, he was seized with symptoms of apoplexy, and died in the course of a few hours. * * * An abscess of the size of a large walnut occupied the posterior part of the prostate, and extended into the space between the bladder and *vasa deferentia* behind the neck of the bladder. * * * An irregular ulcerated orifice was discovered behind the *verumontanum*, through which the probe passed at once into the cavity of the abscess." (p. 146.)]

1807. The *treatment* of retention of urine from inflammation of the prostate, agrees precisely with that of inflammatory retention already described (*par.* 1795); blood-letting, leeches about the *anus*, baths, soothing clysters, poultices to the *perinæum* and the like. If the flow of urine be not thereby effected, the catheter must be introduced, which, however, can never be done without difficulty and great pain; because the swollen gland alters the direction of the *urethra*, on which account also a catheter with a long beak is required, and sometimes must have a large curve (1). If an abscess form in the prostate, the introduction of the catheter is the only remedy; the abscess is either opened by it, in doing which care must be taken not to make a false passage, or it bursts of itself and the pus escapes with the urine (2). The catheter must remain in the bladder till the urine be no longer mixed with pus. **Desault** (*a*) recommends cleansing injections of barley water at the same time.

[(1) In reference to the enlargement of the prostate gland from acute inflammation, **Lawrence** (*b*) says:—" You should avoid, if possible, the introduction of a catheter. There is a pretty actively inflamed substance against which, in its introduction, the point of the catheter will necessarily come, and through which it must pass in order to enter the bladder. The introduction of an instrument, under such circumstances, must be expected to aggravate the sufferings of the patient at the time; and therefore, if you can put a stop to the inflammation, and enable him to make water without the employment of an instrument at all, it will be very desirable for you so to do. Trust therefore to antiphlogistic means, with which fomentations, the use of the hip or warm bath may be combined; and do not have recourse to the use of an instrument, unless these means fail, and there should be an actual necessity for relieving the patient from the danger which the difficulty of evacuating the urine produces. If you come then to the introduction of an instrument, you should be aware of the particular change in the *urethra*, which the swelled state of the prostate produces. The swelled prostate does not diminish the dimensions of the *urethra*, but it alters the course and shape of the canal in that part which goes through the gland; it presses the sides of the *urethra* together, and the swelling of the prostate, the principal part of which is situated below the *urethra*, that is, between the *urethra* and *rectum*, pushes the *urethra* up towards the *pubes*. At the same time, the enlargement of the prostate in size, an enlargement which takes place in all directions, increases the length of this part of the canal. The changes then produced are, first, an elevation of the *urethra*, pushed upwards towards the *pubes*, an elongation of the canal in its prostatic portion, and a pressing together of

---

(*a*) Above cited, p. 229.

(*b*) Lectures in Lancet, 1829, 30, vol. ii.

the sides of it laterally. The best instrument in this case is a *large elastic catheter;* and, indeed, I should observe to you, whether you employ an elastic or a silver catheter in cases of enlarged prostate, you will always find it necessary to use an instrument *of full size,* which will pass on much more easily than instruments of small size. The best instrument is, the catheter made of elastic gum, and you should use those which are made to retain their curved shape without a stilette. * * * If, however, you should fail in introducing such an instrument, you must have recourse to the silver catheter," and " the extremity of the instrument should be prolonged, so as to represent more than a quarter of a circle; * * * a third or a quarter of an inch over that, so as to enable the end of the instrument to rise over the elevated part of the *urethra.*" (p. 811.)

BRODIE advises:—" If there be a retention of urine, the gum catheter, without a wire or stilette, may, in almost every case, be readily passed into the bladder. It is better to use a very small catheter, and to introduce it again, whenever it be necessary to do so, than to leave it constantly in the *urethra* and bladder." (p. 145.) As to the size of the catheter in enlarged prostate, under any circumstances I must confess I prefer the larger, as recommended by LAWRENCE, for the reasons he has assigned, which have been verified by my own experience; and a silver to an elastic catheter, on account of its greater firmness, which prevents mischief.—J. F. S.]

(2) " If there be reason to believe," observes BRODIE, " that abscess is formed, you should endeavour to procure an external discharge for the matter, in order to prevent it bursting into the *urethra.* If the symptoms described exist, and go on for some time increasing, and you discover a fulness and tenderness of the *perinæum,* do not wait for any more certain indication of abscess; but introduce a lancet in the direction indicated by the tenderness and swelling. It will often be necessary to pass it quite up to the shoulders, or even to the handle, before you reach the abscess. But you may do this fearlessly. There is no danger from any ill consequence from such a puncture. If there be abscess, you will, by this proceeding, immediately relieve the distress which the patient suffers, at the same time that you prevent further mischief. If, on the other hand, there be no abscess, the puncture does not make the condition of the patient worse than it was before. Indeed, partly from the loss of blood, partly by removing the tension of the soft parts of the *perinæum,* it is generally useful to the patient, even when it does not answer the purpose of allowing the escape of matter." (p. 146.)]

1808. Swelling of the prostate gland *from varicosity of its vessels* occurs in general, slowly, in old persons after previous hæmorrhoidal ailments, in stoppage of the bowels, after venereal debaucheries, after repeated claps, with sedentary living and good living, after abuse of heating drinks, after frequent efforts in voiding the urine and going to stool. It is always developed slowly. Emptying the bladder becomes more difficult after violent exertion, after heating food and drink and the like. The swollen prostate is felt on introducing the finger into the *rectum,* but is free from pain, and the patient suffers no pain in the passage of the urine through the *urethra.* The varicosity is situated rather in the coverings of the prostate; the substance of the gland itself is therewith sometimes soft and spongy, sometimes tense and hard.

1809. If this disease have any distinct cause, it must be removed. In general, taking away blood from the *perinæum,* clysters of cold water or decoction of oak bark with alum, are sufficient. The introduction of the catheter is in this case always difficult, and the circumstances above mentioned (*par.* 1807) should be always borne in mind. Sometimes a swollen vessel is torn in passing the catheter, in consequence of which bleeding occurs, which gives relief. The inlying of a catheter is here necessary for the purpose of compressing the swollen vessels, and by its accompanying irritation to excite their contractile activity. The treatment is always tedious, and no cure is to be expected under six or eight weeks.

1810. *Hardening* is the most common diseased change to which the prostate gland is subject. It occurs after previous slow inflammation, most commonly after forty years of age, and earlier if the *urethra* be affected, especially in scrofulous subjects and in those who when young have indulged in venery; after repressed eruptions on the skin, and as the consequence of gout and the like (1). It always proceeds slowly; voidance of the urine becomes difficult, and is sometimes completely stopped. The prostatic humour is sometimes exceedingly copious and viscid. The direction of the *urethra* is changed according as the right, left or middle lobe of the gland is swollen. The hardened prostate is felt by examination through the *rectum;* the patient has difficulty in going to stool; a discharge of mucus-like fluid, an unusual sensation about the *rectum* after going to stool, as if the bowel were not completely relieved. All the symptoms described (*par.* 1675) as belonging to stricture, frequently accompany swelling of the prostate (2).

In reference to the secretion of a mucus- or pus-like fluid which may accompany the various diseased conditions of the urinary passages, it may be remarked that the more mucus-like, thick, pus-like deposit which the urine throws down, and which remains loose at the bottom of the chamber-pot, shows a catarrhal inflammation of the mucous membrane of the bladder; the mucus-like deposit which draws out in threads, is elastic like white of egg, and sticks to the bottom of the pot, characterizes disease of the prostate; purulent deposit, and the prostate gland small, soft and flattened mark its destruction by suppuration. If on examination the prostate be uninjured, the pus comes probably from the kidneys (*a*). The mucus from the prostate is not ammoniacal; the mucus from the bladder rarely appears in any great quantity without containing some earthy parts.

[(1) "Chronic inflammation of the prostate gland is," says ASTLEY COOPER (*b*), "the consequence of age, and not of disease. When this disease produces partial retention of urine it should be considered as a salutary process, for it prevents incontinence of urine, which, in old people, would almost constantly take place were it not for this preventive. It makes the urine pass slower than natural, but this may be excused when it is the means of preventing a continual wetting of the clothes." (p. 239.)

BRODIE observes:—"When the hair becomes gray and scanty, when specks of earthy matter begin to be deposited in the tunics of the arteries, and when a white zone is formed at the margin of the *cornea*, at this same period the prostate usually, I might perhaps say invariably, becomes increased in size. This change in the condition of the prostate takes place slowly, and at first imperceptibly, and the term *chronic* enlargement is not improperly employed to distinguish it from the inflammatory attacks to which the prostate is liable in early life. (p. 151.) The chronic enlargement of the prostate may be said to be a disease of a peculiar kind, having no exact resemblance to what we meet with in any other organ. It may, however, in some respects be compared to the chronic enlargement of the thyroid gland, known by the name of *bronchocele*. Like the latter, it is generally slow in its progress, and frequently, after having reached a certain point, if proper treatment be employed, it remains almost stationary for many years. It is, on the whole, a rare occurrence for it to terminate in ulceration or abscess, and the symptoms to which it gives rise, are, with a few exceptions, to be referred to the influence which the disease exercises over the functions of the parts in the neighbourhood." (p. 154.)

Although enlarged prostate is specially the disease of advanced life, yet ASTLEY COOPER says he has "known it occasionally occur in very young people. An instance of this kind happened in Guy's Hospital: a boy was admitted having symptoms of stone, in consequence of which he was sounded, and the operation of lithotomy was about to be performed; the sounding, however, brought on inflammation of the bladder, which terminated in the boy's death. Upon *dissection* it was found that the symptoms for which he had been sounded were produced by an enlarged prostate." (p. 245.)

"I have certainly seen a very few cases of it," (enlarged prostate,) says LAWRENCE, "in young persons, but the great majority of those you have to treat for this complaint are past the middle period of life." (p. 813.)

The part of the prostate gland in general considered as specially enlarged is that which JOHN HUNTER describes as that "*small portion of it which lies behind the very beginning of the urethra,* swells forwards like a point into the bladder, acting like a valve to the mouth of the *urethra,* which can be seen even when the swelling is not considerable, by looking upon the mouth of the *urethra* from the cavity of the bladder in a dead body. It sometimes increases so much as to form a tumour (of which HUNTER gives two engravings, V. and VII.) projecting into the bladder some inches." (p. 188.) It

(*a*) LALLEMAND; above cited, p. 152. (*b*) Lectures in Lancet, 1823, 24, vol. ii.

is this same part which **Everard Home** has dignified with the name of third lobe of the prostate, and claimed the discovery of, without adding anything to what **Hunter** had said about it, except that of the five cases he examined, and on which he grounded his claim, "the appearance," he says, "was not exactly the same in any two of them." (p. 10.) And yet this has got the name of **Home's** third lobe, and is so continually called in spite of **John Hunter's** observation, and the knowledge that the French anatomists have long since been well aware of it under the name *trigone.* In reality, however, so far as I have had an opportunity of observing, the two principal or side portions of the gland are most commonly enlarged at the same time and in the same proportion as this small portion which lies behind.—J. F. S.

"The next thing noticed is," says **Astley Cooper**, "that the urine has a particularly powerful smell, which arises from its being ammoniated in consequence of some urine remaining in the bladder after each discharge. * * * The next symptoms are pain and numbness in the *glans penis;* sense of weight and uneasiness in the *perinæum*, relieved by pressure with the finger; pain in the back of one or both thighs, in the loins. and at the origin of the sciatic nerves, and in the course of the ureters; the *fæces* are flattened, from the pressure made upon the *rectum* by the swollen gland. Persons having enlarged prostate for any length of time, generally have, likewise, *prolapsus ani* and hæmorrhoids. * * * The ammoniacal smell of the urine as the disease advances, becomes highly offensive, and at length the urine itself becomes white or milky; this appearance shows that the inflammation has extended to the mucous membrane of the bladder. If the urine be much retained, it has the appearance of coffee, occasioned by an admixture of blood with it; this leads many practitioners to suppose, for the moment, that the case is one of stone; but if you question the patient for a few moments, your doubts on this point will be removed." (p. 240.)

"Upon dissection," continues **Astley Cooper**, "the prostate is found enlarged sometimes laterally; but most frequently the enlargement is in the posterior part, situated in the middle or third lobe. As the prostate enlarges it is pushed forwards, in consequence of which the *urethra* becomes curved immediately before the *apex* of the prostate; indeed, the coming forward of the prostate causes the *urethra* almost to double upon itself. The curve thus formed is at the *symphysis pubis;* and it is in this situation that the difficulty on passing the catheter in diseased prostate is found. Tracing on the course of the *urethra*, behind the curved part, that canal is seen much enlarged, and the *urethra* itself is considerably elongated, that is, from an inch and a half to two inches; which increase of length is behind the *pubes*, and it is owing to this circumstance that you are under the necessity of carrying on the catheter so great a distance after its point has passed the arch of the *pubes*. As to the prostate itself, we find that it may increase to a most enormous size laterally without giving rise to retention of urine; but that enlargement which occurs posteriorly in the third lobe, frequently occasions retention of urine, for the enlargement is situated immediately behind the orifice of the *urethra;* thus the urine collecting behind the swelling presses it against the mouth of the *urethra*, and forms a complete barrier to its passage." (pp. 241, 42.)

"This tumour," (of the third lobe,) observes **Brodie**, "varies in size from that of a horse bean to that of an orange. When small, it is of a conical form, with the *apex* of the cone projecting into the bladder, and the basis being continued into the rest of the prostate. When large, the basis is often the narrowest part, and it swells out so as to have a pyriform figure towards the bladder. In some instances, by the side of that which I have just mentioned, there is another tumour, formed by one of the lateral portions, also projecting into the bladder. The canal of the *urethra*, where it passes through the enlarged prostate, is generally flattened; and when the latter is divided transversely, the *urethra* appears like a slit, rather than like a cylindrical canal. Not unfrequently the enlargement of the prostate so alters the form of the *urethra*, that, instead of pursuing a straight course through the gland, it is inclined first to one side and then to the other. You would expect the *urethra* to be narrow, in consequence of the increased bulk of the parts by which it is surrounded; and so it is in many instances; in others, however, it is actually wider, being dilated into a kind of sinus, where it lies in the centre of the prostate. I have known such a sinus to contain two or three ounces of fluid." (pp. 152, 53.)

(2) **Astley Cooper** asks:—"How, when diseased prostate exists, are you to know it? What are the diagnostic signs? Why, the enlargement laterally may be readily ascertained by introducing the finger into the *rectum;* but the enlargement of the middle lobe cannot be so learnt. In what way then? Why, by the introduction of a catheter or bougie, and the latter is best; it will be found to stop suddenly; you are then to introduce a catheter for the purpose of drawing off the water; the instrument will

be resisted in its common course. and you must depress the handle a good deal, with a view of tilting its point over the enlarged gland; thus the end of the instrument will be rising perpendicularly, as it were, behind the *pubes*. These, then, are the means you are to employ to obtain a correct *diagnosis*." (pp. 242, 43.)

"The symptoms of retention of urine from enlargement of the prostate, are not very different from those which occur where the retention is the consequence of stricture, but the termination is different. I never saw," says Brodie, "a case in which, under these circumstances, the bladder had given way, as sometimes happens, where there is a retention from stricture; but I am informed that such a case has occurred, and that the bladder ruptured at its *fundus* is preserved in the Museum of St. Bartholomew's Hospital." (p. 155.)]

1811. The *prognosis* in this disease is always unfavourable. Only in the beginning is there hope of being able to disperse the hardening; in advanced cases, the disease may sometimes be diminished, and the patient's condition may be rendered tolerable by the inlying of the catheter. At the first a corresponding antiphlogistic treatment must be employed; afterwards issues and blisters to the *perinæum*, rubbing in volatile liniments with camphor, mercurial ointment, iodine salve, suppositories of *cicuta* and *opium*; internally, *cicuta*, mercury, decoction of *daphne mezereon*, *uva ursi*, and the like, but especially hydrochlorate of ammonia in increasing doses (*a*). If the hardening have a definite cause, the curative means must be directed to it. In introducing the catheter, the points already mentioned (*par.* 1807) must be considered. If an elastic catheter be left in, it does not retain its proper curve after the removal of the stilette, and the urine escapes; it is better, therefore, to use those elastic catheters, which have a permanent curve.

[As to the treatment of enlarged prostate, Astley Cooper says:—"Very little can be effected here by medicine; it is a disease over which medicines have but very little influence. You may, however, give the oxymuriate of mercury in very small quantities, for I believe I have seen it, beneficial. But this is the treatment only for the enlargement of the gland. * * * When no urine whatever can be passed, and when there is great pain at the neck of the bladder," he recommends to "take blood from the arm, apply leeches to the *perinæum*, administer purgatives, and put the patient in a warm bath. If these means should succeed in procuring relief, the best medicine that can afterwards be given for the purpose of preventing a return of the retention, and at the same time of lessening the inconvenience which sometimes attends the complaint, is composed of fifteen drops of the *liquor potassæ*, five drops of *bals. copaib.*, and an ounce and a half of *mist. camph.* If you give fifteen or twenty drops of the balsam it then produces a stimulating effect, and does harm; administer it in the quantity just mentioned, in conjunction with the other medicines, to which may be added two drams of *muc. gum. acac.* * * * Other medicines, as the carbonates of *soda* and *magnesia*, the *liquor potass.*, with *opium*, are occasionally given, but as the latter produces costiveness it is improper. The first medicine will be found the best; it will afford considerable relief, which is all that you can expect, for you must not dream of making a cure." (pp. 243, 44.)

Lawrence says:—"In the case of this chronic enlargement of the prostate, we have not much power of relieving the patient by producing any great reduction of the affected part. * * * By attention, however, to diet, careful attention to the state of the stomach and bowels, by a course of mild alterative and aperient medicines, we can keep the patient perhaps in a tolerably healthy state. Attempts have been made sometimes to reduce this enlargement by seton or issue on the *perinæum* or upper part of the thigh, but it is an inconvenient course of proceeding, and one to which patients are not inclined to submit." (p. 813.)

"When from any cause the vessels of the prostate are more than usually turgid with blood," says Brodie, "the quantity may be diminished, and thus a reduction of size, to a certain extent, may be effected. It is with this view that we recommend topical blood-letting, the exhibition of gentle purgatives, a moderate diet, and, above all, perfect rest in the horizontal posture. But we are not acquainted with any method of treatment which is capable of restoring the gland to its original condition." (p. 173.)

" The treatment of retention of urine from diseased prostate," observes Brodie, " is one of the most important subjects in Surgery. The patient suffers miserably; his life is at stake; he lives or dies according to the skill which you are able to exercise in his favour. The case is altogether different from one of retention of urine from stricture. Bougies are of no service; even if you pass one into the bladder, no urine follows; the parts collapse and close as the bougie is withdrawn." (p. 174.)

Astley Cooper lays down that when " called upon to relieve retention from enlarged prostate, by the introduction of a catheter, the instrument should be fourteen inches in length, and a quarter of an inch in diameter. In consequence of the pressure within, a broad instrument will answer better than a narrow one, for being bulbous at the end it will readily ride over the enlargement. When introducing the catheter, you will meet with no difficulty until you reach the curve which the enlargement of the gland has produced in the *urethra;* the handle of the instrument is to be here slightly raised, for the purpose of insinuating the point through the curved part. Having passed this you are then to depress the handle completely between the thighs, so as to occasion the point of the instrument immediately to rise perpendicularly above the *pubes.* * * * This will cause the point to enter the bladder between the *pubes* and enlarged lobe. * * * " If it be deemed requisite to leave the catheter in the bladder, I should prefer," says Cooper, " one of pewter rather than elastic gum, for it can be curved down before the *scrotum,* and by plugging up the end, the patient may move about as he likes, and at any time he wishes can expel his urine. * * * The pewter catheter should be quite new, and ought not to be worn for a longer period than a fortnight, for the urine acts upon the metal, renders it brittle, and may probably cause the instrument to snap, if the time be extended beyond what I have stated. If there be need of puncturing the bladder for enlarged prostate, it must be done above the *pubes;* but it never need be attempted at all if you can perform your duty." (p. 243 45.)

" In instances where the bladder does not evacuate its contents completely, where there is a constant accumulation of urine within it, the course you have to pursue," says Lawrence, " is to introduce the catheter regularly once or twice in the four-and-twenty hours, so as to draw off the stale urine, and to give the bladder the opportunity of recovering its power of contraction; and after following this up for some time, perhaps two or three weeks, you generally find that the evil is removed, and that the patient recovers the power of completely emptying the bladder. * * * It is necessary that the catheter should be longer than that which is employed under ordinary circumstances; give it the length, perhaps, of fourteen inches, curved as already stated, and always use a catheter of full size. * * * In such cases where the smallest catheter could not be introduced, I have repeatedly succeeded in introducing an instrument of this size with the greatest ease." (p. 813.)

Brodie " rarely uses any but a gum catheter. It gives you rather more trouble to learn the use of the gum catheter, and to become dexterous in the management of it, than it does to learn the use of the silver catheter. When, however, you have once become familiar with the gum catheter, you will generally prefer it to the other; and there is always this advantage in it, that when you have succeeded in introducing it into the bladder, it may, if necessary, be allowed to remain there. A gum catheter may be retained in the *urethra* and bladder with very little inconvenience to the patient, which is not the case with a silver catheter." (p. 175.)

Brodie uses, as did Home, the gum catheter without a wire, as a flexible, or with a wire as an inflexible instrument; and directs that it should not be mounted on a small flexible straight wire, but on a strong iron stilette, having the curve of a silver catheter. He begins with passing a gum catheter without a stilette; if it will enter the bladder, so much the better; it gives no pain, does not lacerate the *urethra,* nor produce hæmorrhage; it may do all that is required, it can do no harm, even in a rough hand; failure will not render it more difficult to pass another instrument. In difficult cases indeed it will not succeed, and then the catheter with the iron stilette must be used. " You ought not to use a catheter so large as to give pain; but for the most part you will find one which is large enough to fill the *urethra,* without stretching it, to be more easy of introduction than a smaller one, which approaches to a pointed instrument, and the extremity of it is liable to become entangled in the tumor of the prostate. The stilette ought to be considerably curved; the reason of this is obvious. (p. 176.) Always bear in mind, in introducing the catheter, that it is to be used with a light hand. It should be held, as it were, loosely with the fingers. It will then, in great measure, find its own way in that direction in which there is the least resistance. If you grasp it firmly, it can only go where you direct it, and it is likely to puncture and lacerate the membrane of the *urethra,* and the substance of the prostate, and to make a false passage instead of entering the bladder. [Most excellent directions, and cannot be too closely followed.—J. F. S.] I generally find," continues BRODIE, "that I introduce the catheter best by keeping the handle of it close to the left groin of the patient. I pass it as far as possible in this position; then I bring the handle forwards, nearly at a right angle to the *pubes*, and not elevating it towards the navel. The next thing is to depress the handle, which is to be done gently and slowly, by placing a single finger on it, and pressing it downwards towards the space between the thighs. In depressing the handle, you generally find the point of the catheter slide into the bladder. Sometimes, however, this does not happen until you withdraw the stilette; and in the act of doing this, the introduction of the catheter is completed." (p. 177.) "I do not mean to lay it down absolutely as a rule, that you should allow the catheter to remain, but I am certain that it is prudent to do so in the great majority of cases. If you remove it, so abundant is the flow of urine which immediately takes place from the kidneys, that you will find the bladder again loaded, and requiring the re-introduction of the catheter within five or six, perhaps even within three or four hours. It will be necessary to use the catheter again after another short interval, and it will often happen, when there has been no difficulty in the first introduction of it, that there is considerable difficulty afterwards. You avoid all this by leaving the catheter in the bladder; and there is another advantage in this mode of proceeding. The prostate is kept in a state of more complete repose, and in one much more favourable to recovery, so far as recovery can take place, that it would be in, if irritated by repeated introductions of the instrument." (p. 180.) "You will *very rarely* fail, by dexterous management, to introduce the catheter, but you *may* fail, nevertheless, in some instances. What is to be done under these circumstances? * * * You may puncture the bladder above the *pubes*, or you may proceed thus: When all your efforts to introduce the catheter have been unavailing; when you feel the point pressing against the tumor of the prostate, and unable to pass over it, apply some force to the instrument at the same time that you depress the handle. It will generally penetrate through the prostate, enter the bladder by an artificial opening, and relieve the patient; and, of course, will continue to relieve him, if you allow it to remain in the bladder. This mode of proceeding has been strongly recommended by some very good Surgeons, and I am not aware that it is attended with danger, although it may not be without its disadvantages. There is reason to believe, that in some cases in which this has been done, the natural orifice of the *urethra* has become so closed, that the patient could never void a drop of urine by his own efforts, being compelled to rely wholly on the catheter ever after. Sir EVERARD HOME has published the history of a case of this kind, which was attended by Mr. HUNTER and himself." (pp. 181, 82.)

With regard to the question of introducing the catheter twice or thrice a day, or, after having introduced it, to leave it there, I must confess I prefer the former, and the use of a large silver catheter; occasionally, it is true, there is some difficulty; but, in general, so far as my experience has proved, the catheter, after having been passed a few times, enters the bladder as readily as a sword into its sheath. On the other hand, I have found that leaving the catheter in for a time, is liable to render the bladder irritable; and that if at the end of a week or ten days, it be withdrawn, it is almost invariably found encrusted, more or less, with calcareous matter, which often renders its withdrawal difficult, and generally causes much pain, if not further mischief, by its roughness.—J. F. S.]

1812. If in *strictures of the urethra*, complete retention be produced either by the use of heating drinks or other excess, or by the progress of the disease itself, the most proper treatment is to introduce a fine wax bougie, which when its point has got into the opening of the stricture, is there held, as is distinctly shown in the vain attempts to draw it back. So soon as it will not move on without using violence, it must not be forced farther, but allowed to remain, till a violent disposition to make water come on, when it must be withdrawn, and the urine generally flows out in a thin stream. Some persons immediately introduce a bougie, which generally passes further, and may remain till the urging to void the urine comes on. At the same time, according to circumstances, may be employed blood-letting, leeches to the *anus* and *perinæum*, baths, soothing clysters, with opium and the like. After repeated introduction of the bougie, in general a thin elastic catheter may be passed into the bladder. If by these means the danger of the retention be removed, then the treatment of the stricture must be commenced according to the former rules.

Amussat (*a*) recommends the employment of forcing injections in cases of retention of urine dependent on stricture. He introduces a flexible cathether, without a beak, down to the obstruction, compresses the *penis*, and screws on to the end of the catheter a gum-elastic bottle, by which fluid can be injected and drawn out again. **Lallemand** and **Begin** (*b*) think it must not be forgotten that forced injections may be useful, if employed with moderation and prudence, and after the use of antiphlogistics and attempts to introduce bougies have been fruitless; but that in such case care must be taken not to use too great violence, for if a plug of mucus be the only or principal cause of retention, it will give way without any violent efforts, and if the parts be dilated by separating them, the power exercised in their contraction being equally on all parts of the *urethra*, which the fluid fills, it will produce severe pain and increase the inflammation; or what is worse, may find some part of the canal which is more friable and weak, and tear it.

[The treatment which a stricture producing retention of urine, will admit of depends principally on the degree of distension of the bladder, and the irritability of the patient. Attempts should always be made to introduce the catheter both before and after drawing blood quickly from the arm, and placing the patient in a warm bath, so as to induce faintness. The catheter should be used with great care and tenderness, to avoid the formation of false passages, which are too frequently made in striving to pass an instrument on these occasions. If the catheter cannot be got in, and the symptoms be urgent, it will be advisable to open the *urethra* from the *perinæum*, and if there be a stricture, to cut through it, so that the cure of the wound and of the stricture may go on together. It is better to resort to this practice early, if the retention be complete, rather than to wait till the *urethra* burst behind the stricture, and extravasation of urine take place; as by so doing the wound heals nearly as after the operation for stone, without much difficulty, and the patient is saved from the trouble and danger of sloughing of the cellular tissue and urinary abscesses. If, on the contrary, the symptoms be not urgent, and the retention have not existed many hours, it is advisable to give tincture of muriated iron in sufficient quantity to produce nausea, by which sometimes, the spasm, which almost invariably accompanies a stricture with retention, is relieved, and the patient passes his water. Purging also of watery stools is also very often efficient in relieving retention, for which purpose a couple of drams of sulphate of magnesia, with fifteen or twenty drops of tartarized antimonial wine, with mint water, may be given every two or three hours, till the medicine operate freely, and then, generally, the water begins to pass. Cutting into the *urethra*, however, should never be deferred when the retention is not, after a few hours, relieved, either by these means, or by the catheter.—J. F. S.]

1813. If by these means no evacuation of the urine can be obtained, and the symptoms become urgent, then puncture of the bladder is required. For this purpose, several writers have recommended *breaking through the stricture*, that is, with a silver conical pointed catheter to penetrate forcibly through the stricture into the bladder, to allow it to remain there several days, and then after a certain time, to introduce an elastic catheter for the purpose of keeping open the canal of the *urethra*. This proceeding, which is especially founded on **Desault**'s observations and particularly defended by **Boyer**, is unquestionably, even in the ablest hands, most highly dangerous, as tearing the *urethra*, false passages, perforation of the bladder, severe pain and inflammatory symptoms so easily follow it. The firmer the stricture and the greater its extension, the earlier are these consequences to be dreaded. Only in strictures of slight extent, which have not been thickened and increased by frequently repeated inflammation from previous attempts with bougies or caustic, does this method seem applicable. Even in these cases, the use of a conical, pointed sound, will easily produce the above-mentioned symptoms, and the use of a thick sound with a rounded end, as proposed by **Mayor**, is still the most

---

(*b*) Dictionnaire de Médecine et de Chirurgie pratiques, vol. xiv. p. 344.

preferable, as being accompanied with much less danger of forming false passages and tearing the *urethra*. Under all other circumstances, if the symptoms be pressing, puncture of the bladder deserves undoubted preference.

Upon breaking through the stricture, the following may be compared:—**Desault**, above cited, p. 244.—**Roux**, Relation d'un Voyage fait à Londres, etc., p. 314. 1815.—**Boyer**, Traité des Maladies Chirurgicales, vol. ix. p. 232.—**Cross**, Sketches of the Medical Schools of Paris.—**Charles Bell**, above cited, p. 148.—**Ducamp**, above cited, p. 79.—**Mayor**, Sur le Cathétérisme simple et forcé, etc. Paris, 1836. Second Edition.—**A. Vidal de Cassis**, Lettre chirurgicale à M. **Mayor**. Paris, 1836.—**Mayor**, Sur le Cathétérisme, en reponse à une Lettre chirurgicale de M. **Vidal**. Paris et Genève, 1836.—Principes fondamentaux du Cathétérisme; in Gazette Médicale, vol. vii. p. 353. 1839.

Of Cutting into the Urethra in the Perinæum.

In retention of urine caused by stricture **Eckström** (*a*) has proposed a less dangerous method of effecting puncture of the bladder, and has pursued it with happy results. After the patient has been placed as in the operation for the stone, a gum-elastic catheter is carried down to the stricture, and held firmly by an assistant, who at the same time, when the stricture is behind the *scrotum*, as is usually the case, lifts the *scrotum* up and stretches the skin of the *perinæum*. The Surgeon, with a pointed bistoury, then makes, nearly the length of the *raphe*, and in the direction given by the sound, a cut an inch and a half long through the skin, lays bare the *urethra*, that the course of the sound and its extremity can be traced. The patient is then desired to strain for the purpose of making water, by doing which, the *urethra* behind the stricture is distended and hard, a cut is now made into the *urethra* towards the sound, and the opening thus produced is enlarged to and through the stricture and sometimes behind it. The point of the fore-finger of the left hand must never for a moment during this operation leave the point of the knife, but must serve as a director. The urine now springs out with violence, and the bladder is emptied; but if this do not readily happen, on account of the palsy of the organ from distension, a female catheter must be introduced into the wound, by the aid of which, the tapping is effected. If no severe symptoms of inflammation or irritation exist, which however, is very commonly the case, a common silver catheter No. 6 is to be introduced into the bladder. When its extremity reaches the wound, that is, the spot where the stricture was, it must be continued deeper, the finger in the wound giving it the proper direction, so that it may not slip from the *urethra*, but go directly into the bladder. When this has been once effected, and the instrument has been left in the bladder two to four hours, there is no fear of the least difficulty in its re-introduction, and a flexible catheter of the same size may be used instead of the former, the wound is bound up with lint, or a compress, dipped in cold water, applied, and it usually heals quickly. For the purpose of getting rid of the existing stricture, catheters of large size must soon be resorted to, but there must not be too much haste, especially before the wound has healed. On the other hand, should there be inflammatory symptoms present, the introduction of the catheter must be stayed, in order not to increase the irritation. The wound in the *perinæum* keeps open by the escape of the urine, and suppurates more or less. Afterwards, the above treatment must be employed (1).

Jameson's (*b*) treatment also resembles this.

Lallemand and **Begin** (*c*) object to this operation the difficulty of finding with certainty and cutting through the *urethra* behind the bulb, especially in fat persons; and the uncertainty of the true condition of the canal of the *urethra*, and of the point behind which it must be opened.

[(1) I leave **Eckström's** description of the mode of cutting into the *perinæum* for retention of urine, just as **Chelius** has given it, for it cannot be better described, but I must deprive him of the credit of having proposed this mode of treatment. To my own knowledge, it has been for more than thirty years the common practice, excepting that a silver instead of an elastic catheter is first introduced down to the stricture as a guide, in St. Thomas's and Guy's Hospitals, and among the Surgeons brought up in those schools. In the many months which **Eckström** spent with us some twenty-five years since, he must have seen this very operation performed again and again in the

(*a*) **Froriep's** Notizen, vol. xviii. p. 155. 1827.

(*b*) Medical Recorder, vol. vii. p. 25, vol. xii. p. 329.—**Leger**; Dissert. de Paracentesi Urethræ in Ischuria Perinæi. Paris, 1778.

(*c*) Above cited, p. 347.

precise way in which he describes it; and it was then so old, that no one, that I am aware, laid any particular claim to the discovery of it. He must not, therefore, run away with the credit of having proposed not only the best, but the only operation for retention of urine which ought to be performed, with the single exception of retention from enlarged prostate, in which, if an operation for retention be ever required, that above the *pubes* must be performed.—J. F. S.]

Of the Catheter and its Introduction.

1814. The catheter is a cylindrical tube of different thickness, straightness and curve, corresponding to the extent and curve of the *urethra.* It may be either firm or flexible; in the former case it is best to be made of silver, and in the latter, of elastic gum or caoutchouc. The length of the catheter is different; for adult women six, and for young females five inches is sufficient; for adult men from ten to eleven, and the several periods of boyhood from five to seven inches. The thickness also varies; for women two lines, for girls a line and a half, for men two and a half lines, and for younger males a line and a half. The front third of a small catheter is slightly curved, and corresponds to the segment of a circle of which the diameter is six inches (1); the other parts of the catheter are straight, and its upper end is provided with a ring on each side. The female catheter is only slightly curved at its front extremity. The front end of the instrument is rounded, and has on either side a pretty large and well rounded hole. The walls of the catheter should not be very thin, and its surface should be well smoothed and polished (2). All catheters should be furnished with a stilette fitting into their cavity, and in elastic catheters it is best that this should be made of iron.

A large catheter is in general more easy of introduction than a small one, because it properly distends the walls of the *urethra,* and is not so easily caught in its folds as a smaller one. In cases, however, where considerable obstruction has to be overcome, as in stricture, a small catheter is passed more easily. One oval opening on the side of the front end of the instrument is better than several smaller ones, or than two on opposite sides; the little holes being easily stopped up in the former, whilst in the latter the necessary strength of the instrument is interfered with. The practice of closing the open end of the catheter with a round plug attached to the stilette is unnecessary. The curve, already directed, of the front third of the instrument, is the most proper; the Surgeon must, however, be provided with catheters of different curves, which are often necessary on account of the particular seat of the obstacle. Elastic silver catheters are useless.

Elastic catheters, with a permanent curve, so that they can be introduced without a stilette, are in many instances advisable.

The double **S** (shaped) curved catheter of Petit is of no value.

Berton (*a*) recommends the use of catheters, one having a curve at an inch, and another at an inch and a half from its tip, so that the lengthening of the axis of the body of the instrument makes, with the prolonged axis of its vesical extremity, an angle, in the former of from 9° to 10°, and in the latter of from 14° to 15°. These curves do not exceed the smallest diameter of the *urethra,* which varies between three and four lines.

Straight catheters were already known to the ancients, as proved by those which have been dug up at Pompeii; they were but very little curved (*b*).

Paré, also the two Fabricius, Rameau, Sietaud, Santarelli, and Cassus used straight catheters for men. Gruithuisen recommended, in 1812, straight sounds in his proposals for crushing stones; but of late they have been more particularly advised by Civiale and Amussat. It is therefore remarkable that Fournier (*c*) should have claimed the priority of discovery of straight sounds, because he has used them since 1815.

(*c*) De l'Emploi de Lithotritie, Sondes droites, etc. Paris, 1829.

[(1) I prefer the catheter with a very open curve, indeed with the point thrown out rather beyond the quadrant of the circle, as recommended by CHELIUS, so as to form with the stem, a curve represented by the long quadrant of an oval, of which the long diameter is double that of the short one. Most Surgeons have a peculiar curve of their own, and those who have much practice in passing a catheter, soon find out that with which they are most dexterous.

(2) The thickness of the walls of the catheter is a matter of great importance, because unless sufficiently stout they are continually broken in the Surgeon's alteration of the curve to suit the particular case which is often requisite; and because, in passing the instrument, if it meet with much obstacle it is liable to be broken in the *urethra*, or even in the bladder. Catheters, as commonly made, are far too slight.—J. F. S.]

1815. The *introduction of a catheter* (*Catheterismus*, Lat.; *Einführung des Katheters*, Germ.; *Cathétérisme*, Fr.) is an operation requiring dexterity and practice, and is not unfrequently accompanied with very great difficulty. It is best divided into three stages. In the *first stage*, the catheter passes through that part of the *urethra* contained in the spongy body. The Surgeon grasps the *penis* behind the *glans*, with the thumb and forefinger of the left hand, without compressing the *urethra*. With the thumb, the fore and middle finger of the right hand he holds the upper end of the catheter smeared with oil or lard, and introduces its point, whilst the handle is towards the navel, into the opening of the *urethra*, and then drawing the *penis* up with the left hand, he pushes the catheter down towards the *perinæum*. In the *second stage*, in which the instrument passes through the membranous part of the *urethra*, when the beak of the catheter has got beneath the arch of the *pubes*, the *penis* is let go, and the handle of the instrument being sunk slowly, and *but a little*, the catheter is now again pushed somewhat forwards, and in the *third stage*, when the beak of the instrument has reached the neck of the bladder, is the inclination towards the thighs first increased, and the catheter pushed slowly forwards into the bladder. When the beak has entered the orifice of the bladder, the handle of the catheter is at last sunk completely between the thighs. It is most convenient for the patient to lie on his back during the introduction of the catheter, but he may either sit or stand; and, not unfrequently, it is more readily passed in one posture than the other. The elastic catheter, properly curved, may be used either with or without the iron stilette.

In the so called *tour de maître*, the handle of the catheter is held towards the thighs, and with its convexity upwards, introduced into the *urethra*. When the beak has reached the *pubes*, the handle is carried round towards the navel with a half turn, and then sunk. This handling is objectionable. In very stout persons the catheter must, at first, be introduced somewhat on one side

[For other observations in regard to passing the catheter, refer back to *par.* 1807 and *par.* 1811, and their notes.—J. F. S.]

1816. The *introduction of the straight catheter* requires the same three stages as have been just described. The patient must kneel on the edge of the bed, with his thighs widely separated, and with the upper part of the body bent forwards, or he may stand or sit upon the edge of a stool in the same posture. The operator sits or kneels before him, and resting his left elbow upon the knee of the same side, grasps both sides of the *penis* with his left hand supine, draws it towards him horizontally and introduces with the right hand a straight catheter of proper size, carrying it with a drilling motion directly horizontal till it reach the arch of the *pubes*; he then draws the *penis* still more forwards, and sinks it together with the catheter, till it has made a right angle without inclining it towards the *perinæum*. The patient then bows himself considerably forwards, so that the *urethra* and neck of the bladder are brought into a line, and the catheter instead of following the upper wall of the *urethra* slips into the bladder.—(MOULIN) (*a*).

According to AMUSSAT's plan (*b*), the Surgeon, standing on the right side or between the legs of the patient sitting on the edge of a bed, with his feet on two chairs, draws the *penis* down with the left hand, till it be parallel with the thighs, introduces the straight catheter with the right hand into the *urethra*, and readily up to the pubic arch; he then draws the *penis* still more down, and holds the beak of the catheter directed upwards, which readily passes through the membranous part to the prostate. If the prostate be healthy, the hand only is usually sunk a little more, and the point of the instrument directed upwards to reach the bladder. If on the other hand the prostate be diseased, the operation is more difficult, and no positive rules can be given. It, however, seems in general to be more advisable not to sink the hand till the instrument reach about the middle of the prostate; the point of the instrument also must be endeavoured to be carried on upon the upper wall of the *urethra*.—(CIVIALE.)

1817. The introduction of the catheter must always be performed with the greatest caution and tenderness; violence may cause severe inflammation, tearing the *urethra*, false passages, and great bleeding.

The obstacles to the passage of the instrument are very various. If the handle of the instrument be sunk too quickly, its beak strikes against the pubic bones, and a firm resistance is felt: it must then be drawn back, and introduced rather deeper before the handle is again sunk. In difficult cases, it may be ascertained by the finger passed into the *rectum*, whether the catheter be beneath the pubic bones. If the instrument be introduced too low, or its beak be found in a wrong direction, when it either pushes the membranous part into a blind sac, or thrusts against a fold of the internal membrane of the *urethra*, it must be drawn a little back, the ring on the right side of the handle attentively observed, and the catheter pushed forwards in the proper direction. The forefinger of the left hand passed up the *rectum* can sustain the proper direction of the instrument. The entrance of the catheter is often opposed by spasm, or by swelling of the prostate. In the former case the catheter is to be held quietly, the *perinæum* rubbed, and then the instrument pressed forward in the proper direction. In swelling of the prostate, the method to be adopted has been already described (*par.* 1807.) Elastic catheters, when stopped by any obstacle, will often pass, if the iron stilette be withdrawn about an inch, and the catheter then pushed forwards. In strictures of the *urethra*, a catheter may sometimes be passed, if a bougie have been previously introduced, and allowed to remain some hours. In difficult cases catheters of different sizes must be used.

1818. When the catheter has entered the bladder it is known by its free motion, by the direction of its handle, which sinks between the thighs, and by the flow of the urine, when the stilette is withdrawn. If the flow be prevented by thick *mucus* or clots of blood, which get into the holes or into the canal of the instrument, the obstacle must be removed by injecting lukewarm water, or by introducing the stilette, or the water must be drawn off by a syringe attached to the outer end of the catheter.

In paralytic retention, pressure upon the lower part of the belly is often necessary to empty the bladder completely.

If there be much difficulty in introducing the catheter, it is best to let it remain; its aperture may be plugged, and it may be fastened by a

---

(*a*) Nouveau Traitement des Rétentions d'Urine et des Rétrécissemens de l'Urètre par le Cathétérisme rectiligne, etc. Paris, 1834.

(*b*) P. EGOT, Dissert. du Cathétérisme exercé avec la Sonde droite. Strasb., 1825. 4to.

double bandage and circles of sticking plaster around the *penis*. The urine must be allowed to escape every three or four hours; and every six or seven days a fresh one introduced, so that it may not get too much softened and encrusted. If the patient cannot bear the inlying of the catheter, it must be introduced as often as needful.

If a stiff elastic or silver catheter remain in very long, or if the *urethra* be shorter than usual, its beak may gradually penetrate the hinder upper wall of the bladder, and cause fatal *peritonitis*. In this case the urine begins to escape after five or six days, or it escapes between the *urethra* and catheter, and symptoms of *peritonitis* arise. To prevent this the catheter must be carefully fastened, not too closely, so that it do not penetrate more deeply than that the urine may escape by its side openings. This may be easily managed, if whilst the urine flows, the catheter be pushed a few lines in, and carefully fastened at the moment it ceases to flow.—(LALLEMAND) (*a*).

1819. The *introduction of the catheter in the female* is much more easy than in the male. The patient being laid on her back, and her thighs somewhat separated, the forefinger of the right hand, with the catheter upon its volar surface, is passed between the *labia* towards the orifice of the *urethra*, which is distinctly felt with its tip as an aperture surrounded with a little puffy edge, and into it the catheter is passed. If it cannot be managed in this way, the parts must be exposed so that the orifice of the *urethra* may be brought into view.

OF PUNCTURING THE BLADDER.

1820. When in consequence of retention of urine, the bladder is so greatly distended, that dangerous results, as mortification, tearing of the bladder, or extravasation of urine, are to be dreaded, and the voidance of the urine cannot be effected by the natural passage, there remains no other means of safety for the patient than emptying the bladder by artificial means, or *puncturing the bladder*, (*Paracentesis Vesicæ*, Lat.; *Blasenstich*, Germ.; *Ponction de la Vessie*, Fr.,) as it is called. This operation is rarely necessary, if the introduction of wax or catgut bougies, elastic catheters, and a mode of treatment corresponding to the character of the retention, have been carefully pursued. It is, however, bad practice to dispense with this operation, by trusting to the violent introduction of the catheter, in cases of insurmountable obstacles in the *urethra*. Puncturing the bladder is not so dangerous an operation as by many supposed; its danger is only much increased when it has been too long delayed.

1821. Puncture of the bladder may be performed in three ways: *first*, above the *pubes*; *second*, through the *rectum*, and in women, through the *vagina*; *third*, through the *perinæum*.

1822. In *puncturing the bladder above the pubes*, the patient must be placed in a half sitting posture in bed. The hair of the *pubes* having been removed, an assistant fixes the bladder with both hands, and holds it in the mesial line, corresponding to the *linea alba*. The Surgeon puts the nail of the forefinger of his left hand upon the upper edge of the pubic *symphysis*; holds with the whole right hand a somewhat curved (FLURANT'S) trocar, lays his forefinger on its convex surface, and places it with the concavity downwards, close above the nail of the left hand upon the white line, and thrusts it through the walls of the belly into the bladder. When the trocar has penetrated from two and a half to four inches deep, according to the thickness of the walls, the operator grasps the tube

---

(*a*) Perforation de la Vessie par les Sondes fixés; in Révue Médicale, vol.ix., p. 299. 1822, Nov.

with the fingers of the left hand, and draws the stilette out with the right. The urine now escapes by the tube, and being assisted by pressure on the belly, is gradually discharged. In order to prevent the sharp edge of the instrument injuring or irritating the walls of the bladder as it contracts, another silver tube with a blunt end is to be introduced through it, through the side openings of which the urine can escape; its other end is furnished with a stay (*a*). For fixing the inner tube, a cleft compress is to be so applied, that the tube may lie in its cleft. The vertical part of a T bandage is to be crossed before and behind the tube and fastened to the girdle part. The outer tube must be fixed by bandages, drawn through the openings in its outer end, to the girdle-piece of a T bandage. To prevent the inner tube drawing back, tapes must be introduced through its rings, and attached to the openings of the outer tube.

The direction to thrust in the trocar an inch to an inch and a half above the pubic *symphysis* rests on the notion that the bladder, in its ascent above the *symphysis*, is separated from the hind wall of the belly. However, in puncturing high, the danger of wounding the *peritonæum* is greater, and the bladder may more easily slip away, when it contracts, after the urine has been voided. In very stout persons, if the bladder be not very full, it may be proper to make a previous cut of an inch and a half long through the coverings in the same place above the pubic *symphysis*, in the white line, till the bladder can be distinctly felt with the finger.

The curve of the trocar should be a segment of a circle of eight inches diameter (Desault); its length must vary according to the bulk of the body, but should not be less than five inches.

It is objectionable to introduce a second tube, with a rounded end, or a flexible catheter, through the first, and to withdraw it, as the urine will escape by the side of the smaller tube.

1823. After the operation, the urine must be discharged by the tube as often as is necessary. If inflammatory symptoms arise or continue, corresponding remedies must be employed. Towards the seventh day, the tubes must be removed to be cleaned. The inner tube must be first withdrawn, and then a curved steel cylinder having been introduced into the bladder, through the canula of the trocar, the canula must be drawn over it, and after having been cleansed, must be returned upon it.

During the after-treatment, attempts must be made in every possible way to restore the natural passage for the urine. When this can be effected, and a flexible catheter have been introduced into the bladder, the tube may be withdrawn; and then, whilst the surrounding coverings are held back with one hand, the opening is to be covered with sticking plaster, and if it will not close, must be frequently touched with lunar caustic.

In changing the tubes care is always necessary for a long while, because the union of the bladder with the hind surface of the abdominal muscles is frequently not sufficiently firm for a considerable time. A previous cut through the covering prevents this adhesion. When, therefore, the reopening of the natural passage is impossible, the trocar must be thrust directly through the coverings, the tubes safely fastened, and the urine discharged less frequently through the tube, which must not be changed before the eighth day, and then only with the greatest care, the patient kept quiet, and when union between the bladder and abdominal muscles has taken place, an elastic catheter may be introduced into the bladder. Schreger (*b*) proposes, by means of loops introduced into the walls of the bladder, by the sides of the trocar tube, to bring them into contact with the walls of the belly, and encourage their union.

(*a*) Zang, Operationen, vol. iii. pt. ii. pl. i. The same mode of proceeding, though with a different object, is directed by Deschamps, Traité historique et dogmatique de la Taille, vol. iv. pl. viii.

1824. In *puncturing the bladder through the rectum*, after having cleared the *rectum* with a clyster, the patient must be laid on the edge of a bed, so that the depending thighs may be bent and supported apart by assistants. The Surgeon introduces his finger oiled into the *rectum*, about six lines above the prostate gland; then carries the curved trocar, with its point retracted, upon it, to the part where the finger determines the puncture should be made. The handle of the trocar is now sunk against the buttock, and at the same time the point thrust forwards out of the canula, and the trocar pushed in the axis of the *pelvis* to the depth of an inch to an inch and a half. The stilette is then withdrawn, whilst the left hand steadies the tube. The urine having flowed through the first tube, a second, with a rounded end, is introduced, and both fixed by means of a cleft compress and T bandage, and tapes drawn through the rings.

1825. *Puncturing the bladder through the perinæum*, is the most ancient practice, but at present almost entirely given up. In this operation, either the *urethra* and neck of the bladder are opened directly by a cut in the *perinæum* or the cut is made upon a staff, (*boutonnière*,) into the neck of the bladder, or the bladder is pierced with a trocar, which is thrust in either *directly* in the middle of a line supposed to be drawn from the ischial tuberosities to the *raphe*, two lines in front of the edge of the *anus*, the point of the instrument being directed first parallel to the axis of the body, and then thrust somewhat inwards; or a cut an inch and a half long is made half an inch to the left side of the *raphe*, beginning beneath the bulb of the *urethra*, and ending by the verge of the *anus*, through the cellular tissue and muscles; whilst an assistant presses the bladder down, the operator's forefinger of the left hand introduced into the wound, ascertains its position, and then upon it he carries a thick grooved trocar, directed somewhat upwards into the bladder. The urine having been discharged, the outer wound is lightly filled with lint, the tube plugged and fastened as in puncture through the *rectum*.

For a careful recital of the various methods of proceeding in puncturing the bladder through the *perinæum*, see

Poller, Ueber den Harnblasenstich im Damme. Erlang., 1813. 8vo.

Upon the various modes of using the Sound, see

Desault, above cited, vol. iii. p. 320.

1826. Although opinions agree upon the undoubted preference of puncturing the bladder above the pubic *symphysis*, and through the *rectum*, to that through the *perinæum*, yet do they differ in regard to the first two modes of operation.

In regard to puncture above the *pubes*, it is considered as easily performed and slightly painful; that by it merely the coverings of the belly and one part of the bladder are injured, where it usually is not inflamed, and where it can be best treated; that the bladder cannot be missed, that the after-treatment is easier, extravasation of urine does not so readily occur, and the tubes, if they accidentally fall out, can be easily replaced, and may be changed and cleaned with little trouble; and that the patient can go about whilst they remain in. On the other hand, the slipping off of the bladder from the tubes after the discharge of the urine, by its falling together, and by the pressure on it, if it descend very low, inflammation and suppuration of the hind wall of the bladder, and thrusting the tube into the *rectum*, are to be dreaded; also if the urine be not completely discharged, that a part of it always remains in the bottom of the bladder.

For the preference of puncturing through the *rectum*, it is alleged that the walls of the bladder and *rectum* are in closer contact, that the trocar has no thick parts to penetrate, and therefore the operation is not painful; that the swelling of the bladder is more perceptible, and failure in introducing the trocar less possible. On the contrary, it is thought that in this operation the bladder may be missed, a blood vessel, or the seminal vesicles, or the *peritonæum* wounded; that its effects are always greater, the escape of the tubes, infiltration of the urine, collection of pus and consequent urinary *fistula*, are to be feared.

1827. The objections to the puncture above the *pubes* are of little value, as in performing it with a curved trocar, and by the introduction of a blunt tube, no injury to the hind wall of the bladder can ensue, and the escape of the urine can be furthered by the proper position of the patient. This mode of operation, therefore, serves generally, but is especially preferable over that through the *rectum* in those cases where the bladder is inflamed or otherwise diseased, in hardening of the prostate, in diseases of the *rectum*, specially in hæmorrhoidal swellings, and if the discharge of the urine through the operation-wound must be long sustained, or throughout life.

As to the objections made to puncturing through the *rectum*, it may be replied, that the injury of the seminal vesicles may be easily avoided by passing the finger in deeply, and thrusting the trocar directly into the middle of the swelling; that wounding the *peritonæum* is not easily possible, because in the elevation of the bladder, the space between the prostate and that membrane is increased; and the slipping out of the tubes, in many cases, cannot produce any inconvenience, as the urine either flows out through the opening, or the bladder again fills. The preference, however, of the puncture above the *pubes* always continues the greatest. As peculiar indications for puncturing through the *rectum* may be held, a very deep-seated bladder, effusion of blood into it, and an overweening dread of the patient about an operation, in which case it can be done through the *rectum*, without his knowledge.

Poller (*a*), in cases where the operation above the *pubes* cannot be performed, prefers that through the *perinæum* to the puncture through the *rectum*, especially if it be foreseen that the retention of urine may be continued a long time after the operation. In the puncture through the *perinæum*, there are also some special objects attainable, as the emptying calcareous concretions in permanent disposition to form stone, and the removal of the danger of ischury in consequence of large stones, which cannot be removed.

[But few Surgeons in England, I believe, at the present time, ever perform either of the operations for puncturing the bladder, as above described, except in the single case of enlarged prostate, in which the operation above the *pubes* should be performed; and indeed, as regards that disease, the necessity for any artificial assistance, beyond that of introducing a catheter, is so rare, that it is scarcely thought of. In all cases the operation of opening the membranous part of the *urethra*, and introducing a catheter into the bladder, which is, and has been for many years past, commonly practised in this country, is the most satisfactory and the most effectual. If there be stricture, it is the Surgeon's fault if the stricture and the retention be not cured at one and the same time; and, to a certainty, it prevents the possibility of mischief from extravasation, as the urine speedily flows by the wound, and is never pent up. There is neither difficulty nor danger in this operation. With common attention, the *urethra* may, in most cases, be found, and a catheter at once passed into the bladder. If it cannot be found, as occasionally happens with young operators, who cut right through the *urethra* before they are aware of it, if the cut be continued more deeply, the bladder must be opened, if the wound be carried up in the axis of the *pelvis;* and if it be not opened, it is not matter of great consequence, provided there be a free external opening, as in the course of a few hours the urine will find its way into the wound, and be readily discharged; and in cases of stricture, if the stricture be so far forward that it be not involved in the wound in the *perinæum*, made by the knife, or by sloughing, if urine be extravasated, it generally relaxes so much, that it can be cured by the ordinary treatment with bougies, or sounds, during the reparation of the wound in the *perinæum*.—J. F. S.]

(*a*) Above cited, p. 47.—Mondière; in Révue Médicale, vol. ii. p. 319. 1841.

1828. When the *pelvis* is so narrow that a child cannot be brought into the world at all by the natural passages, or not alive, the delivery must be effected by some other than the natural way, that is, by the artificial opening of the belly and womb.

1829. The circumstances demanding the Cæsarean operation are *first*, when the antero-posterior diameter of the outlet of the *pelvis* is less than two and a half inches, and the child is alive; *second*, when there is so great narrowing of the *pelvis*, that the dismemberment of the child is impossible.

When it is not quite certain that the child is alive, perforation should be preferred to the Cæsarean operation; as it should be also in misformed children. If the mother be against the operation, her voice must be attended to. In doubtful cases, for instance, when the signs which declare for and against the life of the child are of equal value, the choice of the operation is not to be left to her decision, if she resolve upon it during the labour.

[" The difficulty of deciding upon the operation, according to the indications of the Continental practitioners, is," observes Rigby, " much more perplexing than according to that which is followed in this country. The question here is, can the child, under any circumstances, be made to pass *per vias naturales* with safety to the mother? The impossibility of effecting this object is the sole guide for our decision. In using the operation as a means for preserving also the life of the child, we must not only feel certain that the child *is* alive, but that it is also capable of supporting life, before we can conscientiously undertake the operation upon such indications. This uncertainty as to the life or death of the child greatly increases the difficulty of deciding. Under circumstances where there is reason to believe that, although the child may be alive, it is, nevertheless, unable to prolong its existence for any time, and the *pelvis* so narrow that it can only be brought through the natural passage piecemeal, we are certainly not authorized in putting an adult and otherwise healthy mother into such imminent danger of her life, for the sake of a child which is too weak to support existence. Circumstances may, nevertheless, occur, where the *pelvis* is so narrow that the child cannot be brought even piecemeal through the natural passage; in this case, even if the child be dead, the operation becomes unavoidable. Under the above-mentioned circumstances, it is the duty of the Surgeon to perform the operation; and he can do it with the more confidence, from the knowledge of many cases upon record, where it has succeeded, even under very unfavourable circumtances, and where it has been performed very awkwardly; moreover, it seems highly probable, that the unfavourable results of this operation cannot often be attributed to the operation itself, but to other circumstances. Not, unfrequently, the *uterus* has been so bruised, irritated and injured, by the violent and repeated attempts to deliver, by turning or the forceps, and the patient so exhausted, and brought into such a spasmodic and feverish state, by the fruitless pains and vehement efforts, together with the anxiety and restlessness which must occur under such circumstances, that it is impossible for the operation to prove successful." (pp. 154, 55.)]

1830. In a pregnant woman just dead, the Cæsarean operation should be performed, if pregnancy be so far advanced, that the child is capable of living, if the delivery be not possible by the natural passages, and the mother *actually*, not *apparently*, dead (*a*); in which case the operation must be undertaken as quickly as possible.

[The importance of the actual death of the mother being put, beyond all doubt, previous to undertaking the operation, under these circumstances, cannot be too strongly impressed. A medical friend, on whose veracity I can rely, told me of an instance in which a practitioner in the country, presuming that a pregnant woman labouring under typhus fever was dead, began the performance of the Cæsarean operation, the pain of which arousing her from her deathlike state, she screamed out, and soon died. He lost his practice, and was obliged to leave the place.—J. F. S.]

1831. The Cæsarean operation, partly on account of the very large wound it inflicts, partly on account of the symptoms which follow after, is a most exceedingly dangerous operation. The number of patients

(*a*) Rigaudeaux; in Journal des Sçavans, 1749.

saved is very few, in comparison with those who have died after it. Cases, however, are mentioned, where the operation has been performed, two, five, six, and seven times, upon the same person (*a*). A more favourable result is to be expected, if the patient's health be good; if she have not suffered from previous disease, fruitless labour-pains, or artificial attempts at delivery, and if the operation be undertaken at the right time.

[Michaelis, who has very carefully inquired into the subject, has considerable doubts of the authenticity of many of the cases of repeated Cæsarean operation on the same woman, which have been related by the writers of the seventeenth and eighteenth centuries; for, as he observes, "it must be considered remarkable that no writer, as it seems, relates the circumstance at first hand, that is, from the Surgeon himself; for in No. 3, (the woman who stated she had been operated on thrice,) No. 7, (the ship's captain who declared himself the sixth son of whom his mother had been delivered by this operation, and that she died in her seventh pregnancy, because the Surgeon who had previously operated on her was deceased,) No. 8, (the Minorite, the fifth son of another in this same way delivered of all her children,) and No. 9, (the woman mentioned by Count Tressan, who had been delivered by the Cæsarean operation seven times,) the woman, or the sons who related it, are not of sufficient credit. To this must be added, that some of these histories rest alone upon hearsay, or on suspicious witnesses. Thus was it, for instance, with Count Tressan's case, at a time when, at least in France, literary intercourse was very active, that it seems incomprehensible how Baudelocque, in the *Recueil périodique de la Soc. de Méd.*, vol. v. p. 63 to 74, in which he gives a collection of sixty-six cases, from the year 1752 to 1799, should never at all have thought of this most remarkable case of all; and it is almost beyond belief, that it should remain for Count Tressan to discover such a case." (p. 5.) "This inquiry, therefore, leads to the single result, that the old cases of often-repeated Cæsarean operation must at least remain very doubtful. If, however, we be disposed to give credit one way or other, yet there is little benefit to knowledge from the want of old precise *data*, as, on the whole, the case of Adametz alone shows the possibility of an often repetition of the operation." (p. 6.)

The most satisfactory inquiry into the result of the Cæsarean operation is that made by Kayser (*b*), who divides the history into two periods; the former terminating with Simon's Essay in 1749, and the latter from 1750 to the publication of his own paper. Of the two hundred and fifty-eight cases collected in the first period by Michaelis, to some of which reference has been already made, several rest on very slender authority. Of the three hundred and thirty-eight cases in the second period, one hundred and twenty-eight had a fortunate result, as regarded the life of the mother; whilst two hundred and ten terminated fatally, or a mortality of 62 per cent. It appears, however, from the following table, that the fatality of the operation has been diminishing since 1750:—

From 1750 to 1800 there were 37 successful 80 fatal cases.
" 1801 " 1832 " 54 " 94 "
" 1833 " 1839 " 37 " 36 "
128 210

Or in a decreasing ratio of 68, 63, and 49 *per cent.*

Where labour had lasted more than seventy-two hours, the mortality was 72 *per cent.*; in those where it had continued a less time, only 61 *per cent.*

According to Kayser's inquiries, it appears, that "in one hundred and twenty-three cases the cause of death was stated with more or less accuracy; and it appears that seventy-three women died from inflammation, or its consequences, and twenty-nine from the shock to the nervous system. Internal hæmorrhage occurred in ten, in whom *coagula* of blood were found in the *abdomen*; two died from external hæmorrhage, two

(*a*) Simon; above cited, p. 636.—Le Maistre; in Journ. de Médec., vol. xliv. 1812.—Sommer; in Russischen Sammlungen für Naturwissenschaft und Heilkunst, vol. i. pt. iv. Leipz., 1817.—Locher, J. T., M.D.; in Med.-Chir. Trans., vol. ix–xi. p. 182.

(*b*) Cited at the head of the article. I am very sorry that I have been unable to lay hand on this Inaugural Essay; and am, therefore, compelled to refer to the very meagre extracts from it in the British and Foreign Medical Review, vol. xiv. p. 199, 1842, in which the reviewer observes:—"It is true that this task (that of presenting a list as complete as possible of all well-authenticated cases) is by no means new, but it has never been executed so well as by Kayser." I hope, however, at a future occasion to be more successful.—J.F.S.

from *pneumonia*, one from rupture of the *uterus*, and consequent hæmorrhage, on the seventh day after delivery; one died from *osteomalacia*, and one from the immediate effects of the operation, only twenty-four hours after its completion." (p. 129.)

Michaelis's own case is the most remarkable and best authenticated of any that have been published. The woman was delivered four times by the Cæsarean operation. The account of the first three is given by Feist (*a*), and of the fourth by Michaelis himself (*b*).

The woman was born at Wilster, in Holstein, in 1795, and was so ricketty that she was only able to walk a little when in her twelfth year. She became pregnant, and on the morning of the 18th June, 1826, all other means of delivery being inefficient, the Cæsarean operation was performed by Dr. Zwanck, of Eddelack. The *placenta* was separated and removed immediately after the child, which appeared to have been some time dead, had been extracted, the womb contracting strongly; but this was followed by a severe bleeding, which was stopped by dropping cold water from a sponge, at a height of some feet. The edges of the external wound fell so completely together that there was not need of sutures, and sticking plaster was alone applied. Shortly after three weeks it had healed; before a month she left her bed, and two months from the operation menstruated. On the 21st Jan., 1829, she was again in labour, at the Lying-in Hospital at Kiel, where the Cæsarean operation was performed on her by Wiedemann: the child was born alive. The external wound was brought together with three stitches and sticking plaster, and a small tent left in the lower angle of the wound. On the 21st Feb. she got up from her bed for some hours, and was very well. In the beginning of March the wound was perfectly healed, except a few points of skin and a small sinus, which had not healed when she left the house at the latter end of that month. On the 28th March, 1832, she was in Kiel Lying-in Hospital, again subjected to the Cæsarean operation, which was performed by Michaelis, and the child born alive. The womb contracted imperfectly on the removal of the afterbirth, and there was then first a slight flow of blood from the womb, which was stopped in a few minutes by a stream of water from a sponge. Four sutures were put into the skin-wound, with a small portion of linen into its lower angle, and sticking plaster afterwards applied with a circular roller. The wound was healed, excepting a very small part of the scar, by the 16th May; but on the 25th, a small fistulous passage was discovered running into the womb, which had become firmly adherent to the walls of the belly. On the 10th June the fistula was healed (*c*).]

1832. The favourable time for this operation is that at which nature would, under other circumstances, expel the *fœtus*; when, for instance, *mucus*, streaked with blood, flows from the generative parts; when the mouth of the womb is wide open, the waters have escaped, the head or any other part of the child is perceptible, and the labouring woman has suffered already actual, painful, quickly following labour-pains, nearly approaching convulsions. (Graefe.)

["Although it is so important," says Rigby, "that we should lose no time, still, nevertheless, it does not appear desirable to operate before labour has commenced, to any extent; for, unless the *os uteri* has undergone a certain degree of dilatation, it will not afford a sufficiently free exit for *liquor amnii*, blood, *lochia*, which, by stagnating in the *uterus*, after the operation, would soon become irritating and putrid, in which case they would be apt to drain through the wound, and create much mischief." (p. 155.)]

1833. The preparation for the operation consists in emptying the *rectum* with clysters, and the bladder with a catheter. The instruments required for this operation are a convex-edged and a button-ended straight bistoury, a director, bandages, and several needles. The position of the patient should be horizontal, upon her back, with the upper part of her back somewhat raised, on a narrow table, covered with a mattress; she should also be covered with a cloth at those parts not

interfering with the operation, and should be held by assistants. Her face should be turned from the operator, or covered with a thin cloth.

1834. To prevent the protrusion of the intestines through the wound in the walls of the belly, moderate pressure with the hands is usually employed. **Autenrieth** proposes the previous introduction of ligatures before the womb is opened, and **Rietgen**, a girdle of plaster. **Graefe** more properly makes well-regulated pressure with three sponges, each a foot long, six inches wide, and three inches thick, held by assistants, so that a space about eight inches long, and from three to four wide, is left clear. If intestines be found between the womb and the wall of the belly, which may be ascertained by the yielding elastic condition of the latter, they must be first thrust back by gentle pressure, till a convex, unyielding firm hard body be felt in every direction. At the very moment when the last part of the child escapes, the sponges must be more firmly pressed, by the assistants.

1835. The seat and direction of the cut has been variously proposed.

First. The *Lateral Cut*, on the side where there is the greatest prominence of the belly, or, directly opposite it (*a*), by the side of the white line, more or less distant from it, in or near the *m. rectus abdominis*, between the navel and the pubic bones, and a little obliquely from above downwards and outwards (*b*).

Second. The *Cut in the white line*, beginning from above or below the navel, to an inch and a half or two inches above the pubic *symphysis* (*c*).

Third. The *Transverse Cut*, upon the side, where the womb is most prominent between the *m. rectus* and the spinal column, and between the false ribs and the crest of the hip-bone, above or below the navel (*d*).

Fourth. The *Oblique* or *Diagonal Cut*, the direction of which is from the extremity of the lowest false rib to the horizontal branch of the pubic bone of the other side, obliquely across the white line, so that the middle of the cut falls immediately upon it (*e*).

1836. The choice and direction of the cut, with its accompanying advantages, are not in general determinate, but must be guided by the particular circumstances of the case, especially by the position and direction of the womb, the pretty well known seat of the *placenta*, the position of the child, the size of the space between the navel and the pubic *symphysis*, and the like. As the *placenta* is most usually on the right side, though it may be also on the left, preference has been given to the cut on the left side rather than to that on the white line. In this cut the outer and inner walls are parallel, all fluids escape more readily from the wound; the wall of the belly is at this part thinnest; in opening it no blood vessel is wounded, and the healing of the wound in the *linea alba* is as quick as in any other part of the wall of the belly. In the diagonal cut the womb, after the operation, contracts so that the wound in it does not gape. The same also happens with the oblique cut; in it, however, the wall of the belly is cut through at its thickest part, and vessels are wounded. That part is to be specially considered as the best where the womb and the child can be most distinctly felt.

1837. The operation consists of the following steps:—*first*, the opening

of the belly-wall; *second*, the opening of the womb; *third*, the drawing forth of the child and of the after-birth; *fourth*, the closing of the wound.

1838. The skin and abdominal muscles are to be cut through to the *peritonæum* in one of the directions given, (*par*. 1835,) with a convex bistoury. Any vessel wounded must be tied; a small opening is then made into the *peritonæum* to admit the forefinger of the left hand, and upon it the button-ended bistoury is introduced and divides the *peritonæum* the whole length of the outer wound. A cut is then made in the white line, as no vessel can be there wounded, bearing in mind the thinness of the expanded wall of the belly, with one stroke through the coverings and *peritonæum*. A length of five inches for the cut in the wall of the belly is sufficient, and of four and a half inches for that in the womb is generally to be considered sufficient. The womb now presenting itself in the wound, of a bluish-red colour, its cavity is to be cut into with the convex bistoury to a small extent, and the wound enlarged in the direction of the outer wound, as quickly as possible with the button-ended bistoury introduced on the forefinger. The child, grasped according to its position, by the head or feet, is to be drawn out, but not too hastily, and the navel-string tied and divided. If the opening of the womb fall upon the middle of the *placenta* the cut must be quickly enlarged, the *placenta* cut through, the child pulled out, and the *placenta* separated. If the cut light upon the edge of the *placenta*, it must be separated. If the separated *placenta* present itself in the wound of the womb, it must be separated by a gentle pull upon the navel-string and by a not very quick twist. If this be not sufficient, it must be separated by introducing the hand into the womb.

Wigand's (*a*) proposal of pushing the navel-string with a curved rod through the mouth of the wound into the *vagina* is objectionable.

If the womb do not, by its own contraction, descend into the *pelvis*, it must be cautiously thrust down (*b*).

Various kinds of knives for the Cæsarean operation have been recommended by Stein (*c*), by Flammand, with a removable sheath (*d*), by Zeller (*e*), and Mesnard's knife and scissors (*f*).

1838. After the blood, which has escaped into the cavity of the womb, has been sopped up with fine sponge dipped in warm water, the membranes, which by stopping up the mouth of the womb prevent the flowing away of the blood, are to be removed, the blood poured into the belly gently pressed out, and any of the intestines which have protruded having been replaced, the edges of the wound are brought together by the assistants, and closed with the sutures (*g*), which are introduced with needles of sufficient breadth, in such way, however, that the lower angle of the wound, in which a strip of oiled linen is to be placed, may remain open for the escape of fluid. To support the closed wounds, some pieces of sticking plaster, from four to five inches and a half in width and length, are to be put on, and once and a half surround the belly, their middle placed on the back, and the ends brought forwards crossing in front upon the wound and fixed obliquely below. The open part of the wound below is to be covered with wadding spread with ointment, and over it sticking plaster, and the whole belly supported with a linen girdle, having

strings in front. The patient is then so placed in bed that the lower angle of the wound may, as far as possible, be the most depending part.

[In a case operated on by **Godefroy** of Mayence (*a*), after the womb had contracted the edges of the wound did not come together, but a considerable space remained between them; he therefore passed some sutures of waxed double threads, with a needle, through the whole thickness of the womb. The wound in the wall of the belly was also brought together by passing the needle through its whole thickness, and also through the *peritonæum*. On the eleventh day, the union of the wound appearing firm, the sutures were removed. On the twenty-ninth day no trace of suppuration remained, and the patient left her bed. She recovered, and her child had been saved. Objections have been made by **Desormeaux** to sewing up the womb, but **Godfroy** thinks their danger is exaggerated.

"The most dangerous circumstance in this (Cæsarean) operation is," observes **Michaelis**, "the impossibility of preventing completely the effusion of the secretion from the wound into the belly. The choice of the seat of the operation, as nearly as possible parallel to the white line, seems to be always the most important point, for there most rarely do the two wounds separate from each other. I have already mentioned, in another case (*b*), the remarkable circumstance that the wound in the womb lies transversely, and sinks to the lowest angle of the wound in the wall of the belly; and in other instances I have observed still more remarkable varieties in the wound and its fatal consequences. It may be hoped that this more frequent separation would not be so injurious, as the secretion of the wound discharges itself through the mouth of the womb and the *vagina*. The form which the wound assumes in consequence of the contraction of the womb is, however, unfavourable for this escape; it gapes externally, and lies close together within. Thus was it in my case, in which the whole wound in the womb remained long open, and was in general supported by purely mechanical means. But when the after-pains very soon subside the womb may so close, in consequence of general turgescence, before the oncoming of suppuration, that the cure is quick and without suppuration. It is therefore important that the after-pains should be very early put a stop to, if possible, by the moderate, or even the more active use of opium." (p. 24.)]

1840. The *after-treatment* must be the same as that generally laid down for large wounds of the belly, the state of the patient in regard to her puerperal condition being borne in mind (*c*). The dressings must be replaced when the secretion from the wound has penetrated through, or if there bè any strangulation of the intestines or *omentum*. The removal of the sutures, if not previously required on account of inflammation, should not be before the eighth or tenth day, first indeed, the upper, and afterwards the lower ones. The *vagina* and mouth of the womb should be examined every day, and everything removed which can interfere with the lochial discharge. When scarring begins, a well-closing belly-band must be employed to prevent abdominal rupture, and all exertion avoided.

[**Michaelis** observes, in regard to opium:—"The employment of opium, at first in large, and afterwards in small doses, I consider the most important remedy for the purpose of guarding the nervous system before it become affected by so great an injury as the operation, for moderating the pain and for diminishing reaction." And as to the necessity of keeping the bowels freely open, he says, that "his own experience, and his observation of other cases, have disposed him to it; that there is scarcely a fully described successful case in which the relief of the bowels has not been frequent, indeed where there has not been severe *diarrhœa*. **Adametz** had the bowels moved on the last occasion, from the third to the twentieth day, almost daily six times, and on the fourth day nineteen times; that this was excessive I will not deny; the inconvenience, however, was trifling, and, indeed, had there not been on the fourth day so great a discharge she would have been with difficulty saved. It is, however, difficult to effect the relief at the proper time with the usual means. I believe, however, that we have in ice the safest and, in other respects, the most proper remedy; it at once operates quickly as a purgative if some doses of calomel be given with it." (pp. 25, 6.)]

1841. The following special proposals to diminish the danger of the

---

(*a*) Gazette Médicale, vol. viii. p. 444. 1840. (*b*) **Pfaff**; Mittheilungen, vol. ii. p. 119.

(*c*) Upon the after-treatment, see **Graefe**.

Cæsarean operation may be here mentioned:—*First.* The head of the child should be pressed up against the front of the womb and the belly by the hand passed through the *pelvis* up into the womb, and upon it and the white line, the cut made as far as necessary in order to hasten the expulsion of the child (*a*). *Second.* After the wound is made in the wall of the belly, immediately the womb, the *vagina*, and, if necessary, the mouth of the womb should be opened at a single cut, and the child drawn out of the womb (*b*). *Third.* According to RIETGEN (*c*), a semilunar cut should be made from the crest of the hip-bone to near the pubic *symphysis*, through the skin, whilst an assistant, standing at the patient's left breast, thrusts down the womb from the right side, by which the skin over the region of the wound is stretched. A cut of similar extent through the muscles follows that through the skin, care being taken not to wound the *peritonæum.* The cellular tissue covering the *peritonæum* is to be loosened with the fingers, with the handle of the knife, or with the knife itself, and the cavity of the belly undermined. The straight director is now introduced into the *vagina*, and so directed that its point pushes the *vagina* above the middle of the right *linea innominata.* The operator now thrusts the stem of the director through the wall of the *vagina*, and enlarges the opening with a button-ended bistoury towards the bladder. The director is removed and the cut continued towards the *rectum* upon the right forefinger. If the cut can be so made that an edge of two or three inches of the *vagina* be formed on the right half of the neck of the womb, it must be divided obliquely with the scissors; the wound is then covered and the passage of the child watched. If necessary, the womb also may be cut into on the right side.

RIETGEN (*d*) considers that the wound in the walls of the belly, made as above directed, gives but little width, on account of the oblique direction of the descending fibres of the external abdominal muscle, and that for the extraction of the child a second cut is necessary to divide those fibres transversely. Cutting into the mouth and neck of the womb seems in no case to be dispensed with, and after the first cut has been made through the cavity of the *vagina*, must be immediately proceeded with. By thus doing, the division of the hind part of the *vagina* is unnecessary, and the considerable bleeding which accompanies it is thereby prevented, and what there is may be easily and completely stanched with a sponge dipped in cold water. The best chosen part for the cut into the womb is under that fold of the *peritonæum* which passes upon the round ligament of the womb, and partly lies upon it. ASTLEY COOPER's hernial knife answers best for opening the womb.

BAUDELOCQUE's (*e*) method agrees almost completely with that of RIETGEN. He makes in the right-sided obliquity of the womb a cut upon the left side of the belly along the outer edge of the *m. rectus*, from the navel to an inch or two above the *symphysis.* The waters are discharged through the *vagina*, the legs and thighs bent, and, with the finger introduced at the lower part of the wound, the *peritonæum* is separated throughout the whole extent of the iliac pit, and above the iliac artery. One assistant then draws back the *peritonæum* and intestines, and another keeps the womb in its place by his hand applied to the belly. The operator introduces his hand into the wound, seeks for the iliac artery, and ascertains whether any branches pass from it around the *vagina*, and if there be, they must be tied before he cuts through them. The left hand smeared with oil is now carried into the *vagina*, which is to be lifted into the wound, and then cut into as low down as possible below its insertion into the neck of the womb, and the cut

lengthened to four inches and a half. In left-sided obliquity of the womb, the cut is to be made on the right side. **Baudelocque** calls this operation *Gastroelytrotomy*.

Physick (*a*) proposes making the cut horizontal above the pubic bones, and to dig here beneath the *peritonæum.*

Experience has not yet decided on the value of these several methods, especially upon the various difficulties in bringing the child into the world. The advantage of not opening the cavity of the belly is counterbalanced by the tearing away and separating the *peritonæum*, from which dangerous inflammation, effusion, and collection of pus would necessarily ensue.

[From the account which **Michaelis** has given of the woman **Adametz**, it is evident that, with good reason, he considers a repetition of the operation as more likely to be successful than the first, on account of the adhesions which the womb acquires to the wall of the belly. He observes, that " the growing together of the walls of the belly with the womb had the most favourable influence upon the subsequent operations. This union had already taken place, at the second operation, at one part; in the third, three places had united; in the fourth, the union was complete as far as the cut extended. But I consider that even a partial union has an important influence, by preventing the wound of the womb separating so far from the wall of the belly, that the secretion from the former cannot find a free passage into the latter. It has also the advantage in this operation that if it (the adhesion) be above, the intestines cannot protrude there, but if it be complete, there can be no protrusion. This would be a very untoward condition, if **Merrem**'s opinion (*b*) were correct, that ' in the adhesion the wall of the belly, in the latter half of pregnancy, there would be tearing from the little extensible belly-wall, and thus the flying open of the whole imperfect scar of the womb would necessarily occur;' and that ' in such cases it was not to be supposed that the *fœtus* would be carried its full time.' **Merrem**, on the one hand, draws his conclusions from one single case; but nature, on the other, has other means than theory imagines. These are, that the adherent wall of the belly, or the scar, possesses the same extensibility as the womb itself. The first wound of five inches had, in the second pregnancy, lengthened itself to ten inches, and was four inches broad. In the third pregnancy it was twelve long, and five inches broad; and in the fourth pregnancy still larger. The contraction of the scar after the fourth pregnancy was most surprising, for although the cut itself after some days had diminished to half its length, although it at last diminished from five inches to one, yet was the wall of the belly, at the part where the womb adhered, smooth and free from fold; but where it did not adhere, were two slight transverse folds." (pp. 22, 3.)]

V.—OF GASTROTOMY.

(*Gastrotomia, Laparotomia,* Lat.; *Bauchschnitt,* Germ.)

1842. If a *fœtus* be developed in the Fallopian tube, in the ovary, or in the cavity of the belly, or if by bursting of the womb or *vagina* it escape into the cavity of the belly, and its extraction cannot be effected by the natural passages, dangerous symptoms in regard to the mother are to be feared whether the child be alive or dead, and there be no signs that it can be discharged by the process of ulceration in one way or other by the natural powers, then *opening the cavity of the belly* is required. The other diseases which render this operation necessary have been already mentioned.

The symptoms of an extra-uterine pregnancy are never so manifest, that before the usual period of delivery the operation can be decided on; although, if it can be performed between the second and fifth month, the hope of a successful result is by far greater than when it is undertaken at the ordinary termination of pregnancy; for in these cases the abdominal bowels are always considerably altered, the whole constitution of the patient is greatly disturbed; it is not certain that the *placenta* can be completely separated; and in the separation of the membranes, dangerous bleeding is always to be dreaded. In what way also is the lochial discharge to be got rid of? It must also be remembered that the *fœtus*, in extra-uterine pregnancy, very rarely

---

(*a*) **Dewees**, Compendious System of Midwifery. Philadelphia, 1824.

(*b*) Gemeinde Zeitschr. für Geburtsk., vol. iii. p. 338.

reaches the full period, that on the contrary it not unfrequently remains enclosed and crumpled up in the membranes, which are thickened and hardened; or that in consequence of the irritation of the *fœtus*, inflammation, adhesion of the neighbouring parts, and throwing off the *fœtus* piecemeal, by suppuration, through the openings of the abscess or by the *rectum*, may happen; so that, in most cases, it may be best to assist nature in the discharge of the *fœtus*, in the way just mentioned, by means which encourage suppuration, and the like. According to **Heim** (*a*), most violent pains, and the most pitiable and deplorable condition may exist, and in one case did for ten years.

[It is an important question, whether a womb can be ruptured completely, excepting its peritoneal coat, within which the *fœtus* may be still retained, and so found by the operation of gastrotomy. **Blundell** (*b*) thinks it can, and gives as an example **Barlow**'s (*c*) case, in which it is stated "the *uterus* was very thin, scarcely exceeding that of the *peritonæum*, and equally so throughout the whole extent of the incision." (p. 159.) **Hull** (*d*), however, considered "that the child had escaped through a laceration of the *uterus* into the *abdomen*, enveloped in the secundines, and that **Barlow** had merely divided the membranes, when he fancied he had divided the *uterus*." (p. 73.) But **Blundell** says:—"To me it appears to have been a case of rupture of the muscular substance of the *uterus*, without rupture of the uterine *peritonæum*." (p. 552.) Under such circumstances the operation performed would be merely gastrotomy, and not the Cæsarean.]

1843. When in a tubular or ovarian pregnancy the membranes enclosing the *fœtus* are torn, or by a rent of the womb, the *fœtus* escapes into the cavity of the belly, in which latter case the patient, after severe suffering and labour-pains, feels suddenly easy, and has a sensation of warmth spreading over the belly, the pulse small and quick, and the like, death in general soon follows.

1844. No definite rules can be laid down for the place and direction of the cut. At the part where the *fœtus* is most distinctly felt, and towards which an assistant should press it with his hands spread flat on both sides, a cut of about six inches long should be made through the skin and muscles down to the *peritonæum*, which must be then divided, as in the Cæsarean operation. If the *fœtus* be uncovered by the membranes, it may be removed in any convenient way; if it be enclosed, the membranes must be cautiously separated, the *fœtus*, and afterwards the membranes, if not prevented by adhesion (*e*), and the *placenta* removed. If the *fœtus* be partly in a rent of the womb, it must be taken out cleverly, if possible without enlarging the rent. If separation of the *placenta* be impossible, the navel-string, after having been tied, must be left hanging out of the wound till the *placenta* come away. The dressing and after-treatment are the same as in the Cæsarean operation.

1845. If an abscess or fistulous opening have already formed, it must be cut into or enlarged for the purpose of removing the *fœtus* whole or piecemeal (*f*).

1846. Cutting through the pubic *symphysis* is required in a narrowing of the antero-posterior diameter of the outlet of the *pelvis* of from two and a half to three inches, and in a narrowing of the transverse diameter of the brim and outlet of from two to three inches.

To lay down determinate indications for cutting through the pubic *symphysis* is difficult, as the experiments which have been made upon the enlargement of the pelvic dimensions, after division of the *symphysis* in dead bodies, have presented different results, and it has happened with this operation, as with many others, that it has been, on the one hand, too much vaunted, as on the other it has been unhesitatingly discarded. The indications here given rest on the experiments and practice of Ansiaux (*a*), from which it appears that the pubic bones, after the division of their *symphysis*, are capable of a separation of three inches, without the sacro-iliac *symphysis* being torn; that by this separation the outlet acquires an additional extent of ten lines, and that by the entrance of a part of the child's head into the space between the separated pubic bones, a still further space of five lines is obtained. This proportion may, however, vary in some subjects, which, however, can previously be just as little decided, as can any ossification of the sacro-iliac *synchondrosis*. In deciding, however, upon the results of cutting through the pubic *symphysis* in the dead subject, it appears to me an important circumstance, whether the experiments have been made sooner or later after death.

According to Vrolick's (*b*) experiments, in consequence of the intrusion of the rump-bone in the parting asunder of the separated pubic bones, the increase of the pelvic space is little, and therefore a large restriction of the cut through the pubic *symphysis* is necessary.

Further experience is still requisite to determine how far this operation is applicable in the artificially produced premature labour (*c*).

1847. The operation is to be performed in the following way:—The patient having been placed on her back on a narrow couch covered with a mattress, the *pudenda* cleared of hair, and the *rectum* and bladder, in the latter of which the catheter is to remain, emptied, a cut is to be made at the part immediately corresponding to the pubic *symphysis*, beginning half an inch above the upper edge of the share-bone, and carried down to the *clitoris*, without wounding it. In the direction of this wound every thing is to be cut through, down to the cartilage. An assistant now presses the bladder aside with the catheter, and the operator introduces a button-

(*c*) Reisinger, Die künstliche Frühgeburt, als ein wichtiges Mittel in der Entbindungskunst. Augsburg, 1820.

ended curved strong bistoury at the lower edge of the pubic *symphysis*, and thrusting it along the hind surface, divides the *symphysis* from within outwards. Any bleeding must be stanched by pressure or ligature.

If the *symphysis* be ossified, a little straight button-ended thin saw is to be applied on its upper edge, and division made with some short strokes, during which the assistant draws the soft parts as much aside as possible.

1848. The share-bones now in general separate from each other, which the assistants holding the thighs, allow to take place but very slowly, and the labour proceeds by the natural powers, or is completed by artificial aid. If the bones do not part from each other, the thighs must be slowly separated, till the space between the divided bones has acquired two, two and a half, to three inches extent.

1849. After delivery, the bones are to be brought together, as closely as possible, in doing which special caution must be had that no soft parts be between them. The wound is united with sticking plaster, covered with lint and a compress, and the *pelvis* supported by a close-fitting girdle applied around it.

1850. The *after-treatment* is specially directed by the ensuing symptoms of inflammation. If the bladder or *urethra* be wounded in this operation, a catheter must be introduced. If suppuration, fistulous sores, *caries*, or *necrosis* occur, their treatment must be according to the usual rules. Inflammation of the sacro-iliac *synchondrosis*, consequent on the extension and tearing it has suffered, requires antiphlogistic treatment. If collections of pus form, they should be opened early. An imperfect union of the share-bones, by which lameness or halting is produced, renders the continued application of a firmly-enclosing girdle, perfect rest and the use of strengthening baths necessary.

Chelius; in Heidelb. Med. Annalen, vol. vi.

1851. Upon the heads of newly-born children there are not unfrequently observed soft, fluctuating, generally painless, circumscribed swellings, upon which neither the hair nor the skin is at first affected, and in the interior of which, between the *pericranium* and the skull blood is collected. It is usually seated on the parietal bones, more frequently than on the right side; it has, however, been observed sometimes on the back of the head, and on the forehead. It varies in size from that of a hazel nut to that of a hen's egg, and even more. Sometimes, though rarely, however, it spreads over the whole parietal bone, sometimes, though rarely, it spreads over both parietal bones at once; several of these tumours of different size may also exist on different parts of the skull. Immediately after delivery, they are in general little raised and stretched, but they grow more quickly or slowly in the first few days, when the swelling is less distended and pappy, and fluctuates. The skin covering it, which was at first natural, afterwards assumes a shining, grayish, reddish-blue or violet colour, according to its tension and expansion. Some practitioners (Levret, Naegele, Hoere) have observed, by the application of the hand, whilst the swelling is on the increase, a pulsation, or a peculiar hardness (Hey, Felder) in them, which, however, neither others nor myself could perceive. When the base of the swelling is pressed with the finger, a firm, somewhat raised edge is felt, so that it *seems* as if a part of the bone were lost.

Naegele's opinion (*b*) that the blood swelling occurs only on the parietal bone is in opposition to the earlier statements (*a*) and to the observations of others, (Mombert, Schneeman, Dieffenbach, Burchard,) who have noticed these blood swellings on the occipital and frontal bones.

1852. In its further course, the tumour, if left alone and not immoderately handled, either diminishes gradually of itself, the blood becoming absorbed, and the *pericranium* re-applying itself, or, what is more usually the case, if the swelling be of large size, it undergoes a peculiar sort of metamorphosis, which consists in a thickening of the *pericranium*, and its conversion into bone. The tumour has a peculiar elasticity and parchment-like condition, so that when pressed, it is like a thin plate of metal, which after being pressed down, rises again, and has a peculiar crackling. The swelling gradually becomes harder, and at last as hard as bone, so that like an *exostosis*, it becomes firmly attached to the other bones; and then by degrees, in a space of time, between four and twelve months, it shrinks, and at last entirely disappears, so that not the slightest trace of it can be discovered.

This important metamorphosis, which the blood swelling undergoes, I first (*c*) described, and pointed out its influence upon the treatment. Although Feist has ascribed this observation to Schmitt (*d*), and has been followed by Naegele, who has confirmed it, and though Naegele (*e*) has made no reference to my name on this subject, those, however, who compare my essay of 1828, with those before and since that time, will at least not misplace the plagiarism.

(*a*) Feist, above cited, p. 5–7.

(*e*) Velpeau, Traité complet de l'Art des Accouchemens, vol. ii. p. 596. Paris, 1834. 2nd Edit.

I first mentioned (*a*) that **Schmitt** had pointed out this metamorphosis, and nothing more could be said of **Schmitt**'s observation. For according to **Goelis**, during the treatment of a blood-swelling with caustic, when the tumour becomes as hard as bone, and immovable, and is not dispersed by the maintenance of suppuration and the use of resolvent applications, it must be left alone, and gradually subsides. But **Schmitt** has asserted the directly contrary and decidedly inapplicable explanation of this process, "that the portion of bone lying beneath the swelling, which is at first pressed by the weight of the blood is, after the absorption of the blood, again raised up by an oscillation depending on its own elasticity, to which the increased thinning of the bone, perhaps induced by its maceration in the blood, or the more influential act of absorption, seems to give some probability." It may be further remarked, that this observation of **Schmitt** has been noticed by no subsequent writer, and is not even hinted at in **Zeller**'s Dissertation.

1853. Any other termination of this disease, when left to itself, cannot well happen. It is indeed stated, that if the blood can find no escape, it putrifies, is converted into a bluish, brownish, or soot-coloured substance, which is either thinly or thickly fluid, and has either a stale or putrid smell; and as the thickening of the *pericranium* is prevented by the external discharge of the ichor, the surface of the bone is attacked, its whole thickness destroyed, actual perforation of the skull takes place, and death follows. The blood-swelling may also sometimes run on to suppuration (*b*). From my own observation, however, as well as that of others, I hold it decided that this result, although it may actually take place, is not to be ascribed directly to the blood-swelling itself, since, as **Dieffenbach** has correctly remarked, the excess of blood, and the great nutritive condition of children, strongly withstands this mischievous effect of the pressure of the outpoured blood. Some other influences must, therefore, be added, as improper treatment with destructive remedies, either after opening the swelling, or disease in the child, by which absorption is set up, and the destruction of the bone produced.

The cases in which actual perforation of the skull has been observed, confirm the above stated opinion, inasmuch as in all there was an opening of the tumour. Thus in the case related by **Naegele** (*c*), in which, after opening the swelling, the treatment was unavailing; **Kraus**'s (*d*) case, **Burchard**'s cases (*e*), show also this perforation; but a precise statement of all the previous conditions is wanting, and in one case it is even stated that there was previous catching cold of the child, and disease of the mother, and the treatment was the midwife's.

1854. The *causes* and modes of origin of blood-swellings are as numerous as the various opinions which have been put forward in reference to them, so that many have considered their generic relations as completely in the dark. Experience shows that they occur especially after easy and, more particularly, after quick labours; they have even been met with after breech deliveries, and also after difficult delivery and delivery with the forceps. That the blood-swelling is always accompanied with a diseased condition of the bone, and destruction of its outer table, so that the blood oozes out of the rotten bone as out of a sponge, is contradicted by experience. The roughness of the bone, as well as the destruction of the outer table, which is observed, not in all cases, after opening the swelling, but particucularly when the opening is made late, is the consequence, not the cause, and depends on absorption. The opinion that the blood, by *extensive* bursting, is poured out under the *pericranium*, is not proved by observation; and in opposition to this, as well as to the notion of an original disease of the bone, it

---

(*e*) Above cited.

especially applies that when such are the actual causes the cure of the disease cannot so easily follow. The assumption of a mere mechanical influence has therefore been attempted to be denied, in that this swelling arises more frequently and immediately after difficult delivery, but of which experience proves the direct contrary. Notwithstanding this objection, the origin of these swellings from mechanical influence is, however, the most probable, and is specially confirmed by their, in general, easy and quick cure. We do not, therefore, trouble ourselves about a considerable degree of pressure, but specially about an unequal pressure, and enduring but for a short time, against a projecting or angular part, by which the vessels between the skull and *pericranium* are either torn or so injured, that they afterwards pour out the blood by transudation, in consequence of which, the origin of the swelling is first apparent a few days after birth.

The various opinions brought forward upon the nature of the blood-swellings of the head, may be referred to the three following causes:—*first*, primitive disease of the bone; *second*, diseased condition of the vessels; and *third*, mechanical violence. MICHAELIS holds the first, that in all these swellings, the external table of the bone is wanting, and the *diploë* bared; that the affection of the bone is primary, and the pouring out of the blood secondary. PALLETTA also speaks in a similar way. This opinion, however, is contradicted by many cases, in which, on opening these swellings, the bone has been found smooth, and the change which it, at a later period, somewhat suffers, is considered as the consequence of absorption, depending on the pressure of the blood. This entirely groundless opinion has, however, been recently again put forward by LANGENBECK (*a*), so that the disease appears, in so far a *vitium primæ formationis* as the *tabula externa ossium calvariæ* at one part (!) is deficient, so that the *venæ diploëticæ* are covered only by the *pericranium*, *galea aponeurotica*, and skin. As the *venæ diploëticæ* have very thin walls, so the blood either escapes from them by *rhexis* or by transudation, and distends the *pericranium* into a fluctuating swelling to that point, where the external table is not deficient. The raised edge of bone surrounding the swelling thus points out the place where the two bones lie upon each other, at the boundary of the hollow. If the external table be not wanting, it must, according to LANGENBECK, be very porous, and many vessels penetrate it which serve as *emissaria Santorini*, and are the sources of the blood found in it and beneath the *pericranium*.

A diseased condition of the blood vessels has been, in different ways, assumed as the cause of these swellings. According to NAEGELE, perhaps the varicosity of the blood vessels penetrating the skull, which commence with the growth of the bones of the skull, and are torn previously to, or during birth, may cause the outpouring of the blood, the increase of which after birth may depend on respiration and the new circulation. STEIN assumes an unnatural structure of the vessels; VON SIEBOLD, a similar condition to *nævus maternus* (teleangiectasy?); BRANDAU and HUETER, an original weakness of the vessels, as he has found these swellings only in weakly children; SCHNEEMAN, a loose connexion of the *periosteum* with the bone in but little well-grown children, and the rush of blood in the ensuing respiration; and LANG attributed the cause to the encircling of the neck with the navel-string in weakly children. VON AMMON (*b*) imagines, that according to the pathological observation of HŒRE, OSIANDER, BURCHARD, and others, the vascular system of the bones, the *dura mater*, as well as the *pericranium*, are changed by disease. He himself has sometimes found the veins enlarged upon, and in the bones of the head. The disease, indeed, scarcely depends upon a deficient developement, but is to be considered as consequent on a pathological formative process.

OSIANDER (*c*) asserts, that a small artery, mostly a *vasculum emissarium* tears, either by the blood collecting or from pressure, if the head be squeezed against the one side of the *pelvis*, or by the forceps if unequally applied, and that the swelling therefore takes place, especially on the parietal bones, where the *emissaria Santorini* are found. WENDT, KLEIN, CAPURON, and CARUS attribute it to the pressure on the head during its passage through the *pelvis*; BECKER (*d*), on the skull-bones being thrust in;

(*a*) VON AMMON'S Monatsschrift für Medicin, Augenheilkunde und Chirurgie, vol. i. p. 76.

(*c*) Handbuch der Entbindungskunde, vol. ii. p. 208.

(*d*) HUFELAND'S Journal, vol. lvii. pt. iii. p. 80. 1823.

Neumann (*a*), on the great overlapping of the parietal bones during delivery; Wokurba (*b*), on a distension of the soft parts of the head, accompanied with greater or less pressure, and depending rather on one, than on the coincidence of several causes, in which the vessels, in consequence of the peculiar condition of the infant organism, permit a trickling through of the blood. Bartsch assumes a mechanical violence, which presses on a projecting part of the bone, (as, for instance, the crest of the hip-bone,) for a short time, and unequally, or a violent though short enduring irritation with which the vessels are affected, and which, together with the influx of the blood from the commencing respiration, they cannot withstand, and transude the blood through the weakened walls of the vessels. Paul Dubois (*c*) seeks for the cause in the peculiar structure of the bones of the head. In their still imperfect ossification, they present fibres lying near each other, which from the elevation of the parietal bone, diverge, as from a common focus, towards the periphery. Between these bony fibres there remain small fine clefts, which have not either the length or whole thickness of the bone. They exhibit a correspondently spongy structure, appear to be penetrated with a large quantity of blood, so that after the removal of the *pericranium* and *dura mater*, the blood may be squeezed out of these pores and interspaces. The blood appears therefore during life to be enclosed in the interspaces of the bony fibres by the *dura mater* and *pericranium*, and to stand in close relation with them. If now one or other of these membranes be deficient at one small part, an outpouring of blood takes place, and this may happen from any violence operating on the head of the *fœtus* in its passage through a narrow *pelvis*, in its passage over hard, unyielding walls, or by the application of the forceps. In the same way, on account of an original disposition, the natural connexion of the *pericranium* at a certain point may be so weak, that the impulse even of the circulation may raise it up. In a similar manner, even a disease of the bone, as it increases the influx of blood, can produce outpouring of blood by its destroying the natural connexion of the *pericranium*. Busch (*d*) observed on the hind-head of a child, probably many days dead, and delivered by the violent use of the forceps, a bluish, blood-sac, on opening which, there appeared a communication with the *sinus*. The opinion founded on this circumstance as to the origin of blood-swellings of the head is less to be received, as the case was not that blood-swelling of the head which we are now considering. Flint (*e*) describes a similar case of an outpouring of blood in the hind-head of a child several days after birth, which, as dissection proved, was connected by an opening in the diseased bone with the *sinus* of the brain; on which account, the child died after a cut had been made into it.

1855. The result of the examination of the cavities of these blood-swellings after their previous opening during life, or on examination after death, varies according to the different period of the course of the disease. In the beginning, the blood is found more pale-red, and fluid; afterwards, a thicker, clotted, and blackish blood, even a tough jelly, (Palletta,) sticking to the bone, is collected between the skull and the *pericranium*. The external surface of the bone is sometimes rather wasted but smooth, sometimes rough and eaten away, and, under the already mentioned circumstances, the destruction of the bone is more considerable, and penetrating even to the *dura mater*. At the commencement of the swelling, the *pericranium* is firmly attached to the bone, but afterwards, when ossification begins from the *pericranium*, a delicate bony layer is observed on its internal surface, and, as it were, attached to it (Krauss); and if this ossificating process extend further, a cartilaginous layer with some points of bone, or a firm bony plate appears, which imperceptibly passes into the outer surface of the bone at the base of the swelling, and from which the *pericranium* can be separated as easily as from every other part of the bone. The cavity beneath this bony plate is filled with a grumous, bloody, gelatinous mass. (Burchard.) The upper surface of the skull

(*e*) New England Journal of Medicine, vol. ix. p. 112.

bones is rough, porous, and intimately connected with the gelatinous mass; in some cases even perforated. (Burchard.) If when the *dura mater* have gradually wasted, that part of the bone be examined, in children who have afterwards died, where it has been eaten away, upon removing the skin not the slightest alteration is found, the *pericranium* is in its natural condition, and may be just as well separated as at other parts; on the bone itself there is observed only to the extent which the earlier blood-swelling had occupied, a greater thickening which especially affects the outer table, and on sawing through the bone a greater development of *diploë;* otherwise there is no change of texture in the bone. These slight variations even are probably entirely lost (*a*).

Burchard, from the existence of this bony layer beneath the *pericranium*, has led himself into a mistake, by supposing it *the raised and expanded outer table* of the bone; and hence has arisen the opinion of a blood-swelling, in which the blood is collected *between the two plates of bone.* The falsity of this opinion is proved by what I have above stated as to the course of the ossifying process in blood-swellings. It is further completely irreconcilable with the anatomical character of the skull-bones of a newly-born child, in which nothing can be said of a *diploë*, in its peculiar sense, perhaps even only at certain parts of an external and internal plate.

1856. The *distinguishing characters* of blood-swellings from other tumours on the heads of newly-born children, for instance, the common head swelling, (*caput succedaneum*,) the congenital *hernia cerebri*, the so-called water-bags, and the blood-sacs, which are connected with one of the sinuses (Bush, Flint) are, their circumscribed, elastic, fluctuating nature; their usual seat on the parietal bones, and the impossibility of diminishing them by pressure, in which no symptoms of pressure on the brain arise. It must, however, be observed in reference to congenital *hernia cerebri*, that when, as usual, it happens in the sutures and fontanels, its existence is proved by anatomical examination at other than at the seat of the sutures (*b*). The pulsation which is also given as a characteristic sign in *hernia cerebri*, is not always distinctly perceptible, and even in blood-swellings may be observed; the pulsation, however, in *hernia cerebri* is always more decidedly manifest than in blood-swellings. In *hernia cerebri* an actual opening in the bone can be felt; in the head blood-swelling, when the tumour is not very tense, the bone may be felt by pressing strongly upon it, inasmuch as in these swellings the hard edge at its base is not formed by loss of substance of the bone, but by the swelling of the soft parts, as in common boils. In the blood-sacs connected with a *sinus*, the diagnosis is founded on the perceptible edge of the pieces of bone, and the possibility of diminishing the swelling by pressure. A blood-swelling cannot be confused with *œdema capitis;* from the so-called partial external *hydrocephalus*, in which the water is collected under the *galea aponeurotica* or the *pericranium* itself, is a distinction scarcely possible; the existence of such kind of watery head is rightly doubted. External violence which produces bumps, always more or less injures the skin, which is tinged with blood and discoloured. The *diagnosis* of the blood-swelling may be very difficult when the ossifying process has already proceeded far, and the tumour has not been previously seen. Osiander (*c*) manifestly fell into this mistake, against which only the observation of its peculiar elasticity, and careful inquiry of its earlier condition can guard us.

(*c*) Handbuch der Entbindungskunst, vol. ii. *par.* 205. Tubing., 1821.

Osiander believes the common blood-swellings cannot be confused with the congenital *diseased bone swellings*, which certainly belong to those very great rarities, in which the bone is swollen in the *diploë* (?), in which swelling however the upper table is never wanting, but only *spongy* and *raised*. With such swellings of the bone nothing can be done; and cutting into them would certainly always be followed by death. That Osiander here has mistaken blood-swellings which had already gone on to ossification, and has given of them, as has Burchard, a false description, there can be no doubt. In a case, where two swellings on the right parietal bone, the one more than the other presented the above-mentioned conditions, and in which several practitioners asserted a suspicious degeneration of the bone, I made known the true nature of the disease and advised its being opened; and its fortunate result verified my opinion, coagulated blood escaping after the opening. In another case which I showed Naegele, he admitted that he should not have known it for a blood-swelling (*a*).

1857. The *prognosis*, if the disease be properly treated, is generally not unfavourable, if it be unconnected with *syphilis* or atrophy. All blood-swellings on the heads of newly-born children either disperse in the space of fourteen or twenty-one days by absorption of the blood poured out beneath the *pericranium*, or they subside after a longer time, after the swelling has become as hard as bone, very gradually. From the fear of the bone becoming affected from the continuance of the blood under the *pericranium*, from the opening of the tumour being omitted or delayed, which is not supported by experience, and from not knowing what happens to these swellings if left alone, persons have been led to the proposal of the most different reasons for their treatment. At least I have seen, up to the present time, in many cases where the *pericranium* has been ossified, very large swellings subside without a single accident, in the course of a year.

1858. The *treatment* of blood-swellings aims either at their dispersion by increasing the activity of the absorbents and thus removing the blood, or emptying the blood by opening the swelling.

1859. The *dispersion of these tumours* is usually attempted by vinous, aromatic applications, by applying a solution of hydrochlorate of ammonia, lead wash diluted, arquebusade, decoction of oak bark, and the like. It appears, however, that with the application of these remedies, the necessarily accompanying slight compression perhaps contributes more to the dispersion than the mere operation of the remedies. I know instances in which the dispersion of these swellings followed simply from compression with a pad and a close-fitting hood; and it must also not be forgotten that many of these swellings, especially if they be small, entirely subside without any treatment. Henschel and Schneemann have recommended as the most efficient remedy, compression by means of a hood, lined opposite the seat of the swelling with several folds of tinfoil. In no case should very irritating or cold applications, or much compression be employed; by which in manifold respects injurious influence might be excited. I doubt whether there be a single case of blood-swelling of the head of newly-born children, where the tumour was left to itself, which ever had any bad result; or in which the opening would have been considered necessary: and as I formerly asserted on this point, that if in a space of from ten to fourteen days, the swelling under the above-named treatment had not diminished, but remained equally large, and was of unusually large size, it was most advisable to open it, so can I now from repeated experience assert that this practice is to be considered safe and free from danger. It must, however, apply only to those cases which occur very

---

(*a*) My observations; in Heidelberg. klinisch. Annalen, vol. iv.

rarely; so that the opening is only the exception, and not as most writers on this disease have laid down, to be taken as the rule. If the process of ossification have already begun, nothing must be done except leaving the swelling entirely to itself, because after opening, the upper wall cannot, on account of its firm nature, apply itself, and a tedious suppuration ensues, as I have in one case witnessed.

An early opening is equally objectionable, because in consequence of it there is often a considerable escape of pale-red blood, whilst in a later made cut black blood is discharged in no great quantity.

The application of lunar caustic upon the swelling, and the keeping up suppuration after the separation of the slough for the purpose of favouring the dispersion of the tumour, as recommended by **Goelis** (*a*), is on many grounds objectionable (*b*).

1860. Opening the swelling is best done with a lancet to such extent as to allow the blood to flow out freely. Some threads of fine lint must be placed between the edges of the wound, and fixed with sticking plaster; and over all a compress and close-fitting hood. For the first few days ordinarily a somewhat bloody, afterwards a yellowish serous, and at last a somewhat purulent fluid is discharged; but on renewing the dressings after a few days the integuments have generally become in some degree united to the skull, and the cure soon follows. If, after the opening of the swelling, the surface of the bone appear rough, the dressing in this simple way must be employed.

Opening the swelling by a crucial cut or throughout its whole length, is unnecessary and improper; the introduction of a seton (**Palletta**) is objectionable. The simple puncture of the swelling with the lancet, and closing the opening, may, if at the same time dispersing remedies and a compress be used, effect a cure. Should the fluid collect again, the united edges of the wound may be easily separated with a probe, and the fluid having been discharged, the cure follows. When **Dieffenbach** observed, after small incisions, a secretion of ichor for several weeks, without the skin adhering in the least, and after a free opening that a speedy cure ensued, and when **von Ammon** supposes that the blood-swellings more frequently heal artificially than by the natural powers, the cut for assisting the discharge of the blood, the production of an adhesive inflammation, or of a fresh natural activity, must be carried deep down to the *pericranium*, even into the *diploë*, and not merely through the whole extent of the swelling, but into the sound parts of the neighbouring coverings of the head, inasmuch as small cuts, which are rather punctures than cuts, produce venous bleeding from the varicose vessels, difficult to be stanched, and which can only be stopped by a proper long and deep cut. My own experience and that of others so completely contradicts this, that these bad consequences must certainly be ascribed more to some other circumstances in the treatment, the time of the operation, and the like, rather than to the kind of opening. Further, as regards **von Ammon's** opinion, it may be observed that what I have already sought to employ against **Burchard**, applies to it also.

Hoere (*c*) describes a case of a simultaneous collection of blood between the *pericranium* and the skull, and the *dura mater* and the skull, with which there was at the same spot a penetrating cleft of the bone. The internal swelling was as large as a pigeon's egg, and had formed a pit in the brain of corresponding depth. The outer table of the skull was unchanged, but the inner was eaten away, and at one place entirely wanting; at one spot also production of bone seemed to have again begun. If **Hoere** suppose that the internal swelling had arisen first, and that by the changes of the bone the fissure had been dependent on the birth, when the blood collected beneath the *pericranium* had sunk down during birth, for which the destruction of the inner table spoke; yet is this a merely voluntary assumption, and incorrectly has been founded upon it a division of blood-swellings of the skull into *internal* and *external*, a division which **Burchard** assumed, and added the collection of blood between the plates of the skull as a third form of these swellings, against the admission of which I have already given reasons.

II.—OF HÆMATOCELE.

(*Hæmatocele*, Lat.; *Blutbruch*, Germ.; *Hématocèle*, Fr.)

Pott Percival, The Chirurgical Works of, vol. ii. p. 382. London, 1783.

Follett, Journal de Médecine continué, vol. xiii. p. 422.

Cooper, Sir Astley, Observations on the Structure and Diseases of the Testicle. p. 209. London, 1830. 4to.

Brodie, B. C., A Clinical Lecture on Hydrocele and Hæmatocele in London Medical Gazette, vol. ix. p. 926. 1832.

Curling, Thomas B., A Practical Treatise on the Diseases of the Testicle and of the Spermatic Cord and Scrotum. p. 236. London, 1843. 8vo.

1861. *Hæmatocele* is a large outpouring of blood into the various coverings of the testicle. The extravasation may be seated in the cellular tissue of the *scrotum*, in the vaginal tunic, or in the testicle itself.

[This division of hæmatocele is similar to that made by Pott; but among most modern British Surgeons the term is restricted to a collection of blood within the vaginal tunic alone. Herbert Mayo (*a*), however, observes:—"This term is given to two affections, one effusion of blood, the other of sanguinolent *serum* into the *tunica vaginalis*. The latter, I believe, may alternate with hydrocele, the secretion being from an accidental cause dark and turbid at one time, clear and serous at another. It may likewise arise from blood being mixed with the *serum* of the hydrocele, in consequence of a bruise on the *testes*, or from a vessel having been punctured in tapping a pre-existing hydrocele."]

1862. The yielding nature of the cellular tissue in the *scrotum*, the size of its cells, and the absence of fat render the production of this outpouring of the blood easy, and permits a very considerable enlargement. The usual cause is external violence, a blow on the *scrotum* and the like; also a wound in which the bleeding vessel cannot be tied may give rise to it. That severe compression of the abdominal walls whilst the breath is held should cause hæmatocele is unlikely. According to the size of the injured vessel is the hæmatocele more quickly or slowly formed. The colour of the swollen *scrotum* is more or less violet or dark, and the swelling, although tense, is usually not painful. Similar ourpourings of blood, in women, occur in the *labia*.

[This form of the disease, Pott says, "consists in a rupture of and effusion of blood from a branch of the spermatic vein in its passage from the groin to the testicle. In which case, the extravasation is made into the *tunica communis*, or cellular membrane investing the spermatic vessels." (p. 385.) Upon this point Brodie justly observes:—"The tissue here (the cellular tissue of the *scrotum*) is exceedingly loose as in the eyelids, and slight injury will rupture vessels and produce *ecchymosis*; but the name of hæmatocele is here improperly applied." (p. 927.)]

1863. This outpouring of blood, although it may be considerable, generally disperses by antiphlogistic treatment, cold applications, the testicle being at the same time supported with a bag truss, and rest being enjoined. If this do not happen, and the swelling become more considerable, the collected blood must be discharged by several deep cuts, the bleeding vessels sought for and tied; or if this be not possible, the bleeding must be stanched by inserting lint moistened in some astringent wash, and by applying a close fitting bag truss.

(*a*) Outlines of Human Pathology, p. 561. London, 1836. 8vo.

1864. The hæmatocele which arises from a collection of blood in the vaginal tunic of the testicle is either consequent on a wound of a vessel of that tunic in puncturing a hydrocele, or of the tearing of swollen vessels which, in the quick drawing off the water, are suddenly deprived of their accustomed pressure, or it may arise from a bruising of the *scrotum*. In the former case the swelling in general arises soon after the puncture, in the second it is more tedious. The *diagnosis* is in other respects easy. In the third case the swelling has a resemblance to hydrocele; it, however, generally arises more quickly, and is not transparent. If the blood be partially coagulated, the swelling may, on account of its finer and irregular character, be mistaken for a sarcocele. Not unfrequently a hæmatocele of distinct portions occurs without violence, but from transudation of blood, especially in gravel, and cannot be distinguished from a hydrocele; or there may be a bloody exudation with varicosity of the vessels in old and very large hydroceles, in degeneration of the vaginal tunic and so on, which is only discovered in the operation for hydrocele. Sometimes in old persons mortification and death quickly follow (*a*).

[BRODIE says:—"Hæmatocele most frequently occurs in combination with hydrocele, the blood being mixed with the fluid contained in the *tunica vaginalis*, and partially dissolved in it. If the quantity of blood be small, which is most frequently the case, the solution is complete; but when otherwise, *coagula* are formed, which remain undissolved." (p. 927.) Upon this point I must observe that I do not recollect to have seen a single instance in which hæmatocele followed the operation for hydrocele, though I am well aware that the disease is occasionally so produced, in consequence of the trocar wounding the testicle, if the vaginal tunic be thick and rather more than ordinary effort be used for its introduction; but I have never seen such a case, though I have seen many of hæmatocele produced by a blow.—J. F. S.

BRODIE mentions a remarkable "case, where the extravasation was so great that the *tunica vaginalis* was ruptured, and the blood escaped in large quantity into the cellular membrane of the *scrotum*." (p. 927.)

ASTLEY COOPER mentions the case of "a gentleman who had a large pyriform swelling in the left *tunica vaginalis*, which had never been painful, and which had an obscure fluctuation, but was not transparent. He made an incision into it, and discharged near a pint of fluid blood. This swelling had not succeeded a blow, but was imputed to excessive exertions which this gentleman had been in the habit of making." (p. 214.)]

1865. Outpouring of blood into the vaginal tunic is rarely dispersed. Cold resolving applications and the treatment above advised (*par.* 1863) may be attempted, but if of no advantage, the vaginal tunic must be opened, the blood discharged, any wounded vessel tied, and in a decided hydrocele the necessary treatment may lead to a radical cure (1).

[(1) Upon this point CHELIUS is in error, so far as I have had opportunity of observing these cases, as the blood is generally absorbed without difficulty in the course of two or three weeks. The contrary is the exception.—J. F. S.

Of the length of time which a hæmatocele may exist without causing trouble ASTLEY COOPER relates a remarkable instance, in which a hæmatocele "as large as the double fist had existed seventeen years, had not been attended with any pain, and its size and weight were the only inconveniences it produced. Its cause the patient attributed to a blow, in hunting, from the pummel of the saddle, which gave him great pain for a short time. The *testes* and *epidymis* could be felt at the lower part of the swelling, and above it to the ring, a solid substance united with a fluid could be perceived. It was not in the least transparent, and he had never suffered pain in it. The swelling was opened, a coffee-coloured fluid, blood and solid substance of a brownish-yellow colour was discharged, the *tunica vaginalis* was excessively thickened, looking like the densest parchment." In the course of the same day, after riding home in a coach, "he was seized with a profuse hæmorrhage from the *tunica vaginalis*, and fainted.

(*a*) Exercitationes Pathologicæ, p. 201.

Much constitutional excitement followed, clots of blood and profuse purulent discharge ensued, and after six weeks he got well." (p. 210–12.)

More commonly, however, if the outpoured blood be not absorbed in a few weeks, it becomes an irritant, suppuration is set up within the vaginal tunic to get rid of it; the *scrotum* on that side becomes of a dusky-red colour, and more or less tender, and, if left alone, will sometimes point, and then clots of blood with bloody pus are discharged, and continue till the whole sac is emptied, when healthy suppuration follows, and the cavity of the tunic is obliterated. I have seen two or three instances of this kind. When its existence is suspected it is best to make a free cut from top to bottom of the vaginal tunic so as to empty its contents at once, healthy suppuration soon comes on, and the patient is cured.—J. F. S.]

1866. As to the outpouring of blood into the substance of the testicle, it is probable that it may be confused with some organic changes of that organ; and if, in consequence of a violent bruising, blood be extravasated within the *tunica albuginea*, and the above-recommended treatment, castration must be considered necessary.

[As the formation of hydrocele has been already shown (*par.* 1199, *note*) to take place occasionally in the spermatic cord, so does hæmatocele, as was noticed by Pott, who says:—"The last species of this disease (hæmatocele) arises from a bursting of a branch of the spermatic vein, between the groin and the *scrotum*, in what is generally known by the name of the spermatic process. This, which is generally produced by great or sudden exertions of strength, feats of agility, &c., may happen to persons in the best health. * * * The effusion or extravasation is made into the cellular membrane which invests and envelopes the spermatic vessels, and has something the appearance of a true hernia." (pp. 391, 92.) If discutient remedies be unavailing, Pott recommends the swelling should be cut into, and either the bleeding stanched with styptics, or, if the vessel be large, that it should be tied singly, and if that be insufficient, that even the testicle should be removed, and the whole end tied.

Curling says:—"An encysted hydrocele of the spermatic cord may be converted into a hæmatocele. In the Pathological Museum of St. Bartholomew's Hospital there is a preparation of encysted hæmatocele of the spermatic cord. The cyst is empty, but it is described to have contained blood, and its walls are deeply stained with the colour of partially decomposed blood. Its lining membrane is wrinkled and coarsely granular, and the tissues around it are thickened, tawny, and adherent together. I lately examined a preparation in the Hunterian Collection, which I have no doubt is a specimen of old encysted hæmatocele of the spermatic cord. There is a good sized cyst, lined by a membrane, polished, and a little wrinkled, filled with a soft tawny-looking granular matter, resembling the altered coagulum of blood which I have observed in ordinary hæmatocele after long maceration in spirit. The tissues around the cyst are thickened and indurated, just like those around an old hæmatocele of the testicle." (pp. 249, 50.)]

III.—OF OUTPOURING OF BLOOD INTO THE CAVITIES OF JOINTS.

1867. A collection of blood in the cavity of a joint occurs rarely, and is only the consequence of a violent bruise or wrench of a joint, or of a wound, if the blood cannot escape through the outer opening. The quick occurrence of the swelling after one of the above-mentioned causes, distinguishes it from other swellings.

[Hey (*a*) mentions an instance of blood getting within the capsular ligament of the knee-joint in consequence of a wound, but no harm followed, and it was absorbed without having caused any inconvenience.]

1768. The *treatment* consists in the use of cold applications, general and local antiphlogistic remedies, by which dispersion is effected. In other respects the rules laid down (*par.* 557 and onwards) must be borne in mind.

SCHREGER, B. G., De Bursis mucosis subcutaneis; cum ix. tab. Erlang., 1825. fol.

MAYO, HERBERT, Outlines of Human Pathology, p. 110. London, 1836. 8vo.

1869. *Dropsy of a mucous sac* produces a swelling, fluctuating, peculiarly elastic, in general not, but sometimes very painful; most generally occurring on the hip- knee- ankle- wrist- elbow- and shoulder-joints, and having the skin over it of its natural colour. At first it is circumscribed, and does not extend over the whole joint; its extent, however, may be very considerable.

[MAYO says:—" The *bursa* situated between the *latissimus dorsi* and the inferior angle of the *scapula*, is liable to become distended with a very considerable quantity of fluid." (p. 111.) He also observes, that " pressure will cause the developement of subcutaneous *bursæ* in the cellular tissue, where they previously had no existence." (*ib.*) This is the comman opinion, but it must be taken with some caution, as the number of mucous bags just beneath the skin is much greater than commonly supposed, so that one of them originally existing, may only have become dropsical, and then first only have attracted notice. There seems, however, little doubt that they are actually produced sometimes, when a part is subject to great pressure.—J. F. S.]

1870. This disease may be produced by external violence, by spraining the joint, or by pressure; or by cold, rheumatic, gouty or scrofulous disease, and after the frequent use of mercury. The cause of the unnatural collection appears to be always an inflammatory condition of the inner membrane of the mucous sac, which corresponds in its physiological and pathological nature to synovial membrane. This inflammation is at first often very great, and appears to be related to the cause on which it depends. The fluid is mostly thin, sometimes more consistent, jelly-like, and often contains a great number of cartilaginous concrements, of whitish colour, smooth surface, and different size, often felt distinctly on examination of the joint, and made up of coagulated *albumen*. The membrane of the mucous sac is often very much thickened, and nearly cartilaginous. If the swelling be highly inflamed, it may run on to suppuration, the pus may be poured out beneath the skin, and considerable destruction and fistulous passages may ensue. This is very frequently the case upon the front of the knee-joint.

Undoubtedly here belongs a peculiar kind of encysted swelling, described by CRUVELHIER (*a*), which is most frequent on the front of the wrist, less so upon its back, and more rarely at the ankle-joint, but always occurring in the neighbourhood of synovial capsules and tendons, most commonly divided into two halves connected with, but beneath

(*a*) Essaies sur l'Anatomie Pathologique en général, vol. i. p. 306. Paris, 1816.

each other, by an opening in the tracks of two neighbouring ligaments, and containing besides a quantity of serous or synovial fluid, a larger or smaller number, even up to a hundred, of oblong, smooth bodies, composed of numerous layers, from the size of an oat, to that of a bean.

The mucous sheaths of tendons are similar to mucous sacs, and the swellings developed in them, which contain a thin or more consistent fluid, (*ganglia*, Lat.; *Ueberbeine* Germ.; *ganglions*, Fr.,) must, at least the greater number of them, be classed with dropsy of the mucous sacs.

[Partial enlargements of the sheaths of tendons by the collection of a fluid like *synovia* within them, forming what are commonly called ganglions, sometimes occur in very uncommon situations; I have in one or two instances seen a ganglion as big as a pigeon's egg, and very hard, from its fulness, in the inner hamstring, just above the knee-joint. I have at present under my care, a young man, who after a little more than ordinary exertion, had a swelling come almost suddenly just where the tendon of the *m. sartorius* turns round the upper part of the shin-bone, and extending up into the ham, so as to have somewhat the appearance, at first sight, of a popliteal aneurysm, and nearly as large as a goose egg, tense and free from pain. In the course of a fortnight it subsided under the use of cold evaporating lotions.—J. F. S.]

1871. Among the dropsies of the mucous sacs, those are most frequent which are seated on the knee-cap; they are painless, without any alteration of colour in the skin, soft, elastic, compressible, of a spongy feel, mostly oval, and always distinctly defined, or they are bean-shaped, puffy, hanging down from the knee, or more elevated in breadth. However variously their extent may exceed that of the knee-cap, yet is their base, however, always alone confined to it, and has no other attachment; and although the mass itself be movable in every direction, yet the base can never be moved from this one spot. The fluid it contains is *serum*, in which are frequently similar little bodies, to those found in the mucous bags (1). SCHREGER (*a*) calls this swelling, which is usually known by the name of *Knee-fungus* (*Fungus genu*, Lat.; *Knieschwamm*, Germ.) or as *dropsy of the mucous sac on the head of the shin-bone*, an *encysted dropsical swelling on the knee-cap*, (*Hygroma cysticum patellare*, Lat.; *Wasserbalggeschwulst auf der Kniescheibe*, Germ.,) in which the serous fluid is contained in a space naturally existing upon the upper surface of the knee-cap, (*bursa subcutanea patellaris*,) but not in the mucous bag on the head of the shin-bone (*b*), or in the fine plates of the cellular substance (*c*), or in a newly-formed sac like a true encysted swelling (*d*). This swelling upon the knee-cap is to be classed with that seated on the *olechranon*, in the *bursa anconea*, appears mostly in old people, and in which the above-mentioned little bodies are observed in quantities. These two swellings, especially that on the knee-cap are often accompanied at first with violent inflammation.

The mucous sacs are capable of a degeneration in which an homogeneous, tough, moderately fibrous mass, connected with their walls, is formed, and gradually enlarges to an enormous size. I have noticed swellings of this kind on the knee-cap and at the elbow-joint, and have removed them successfully. All other treatment is useless.

[(1) This enlargement of the mucous bag upon the knee-cap is so very frequent among women servants, that it has acquired, and usually goes by the name of "Housemaid's knee." It is also extremely common to observe the same kind of enlarged bag upon the back of the *olechranon*, but without the person's elbow having been subject to any frequent pressure.—J. F. S.]

1872. The *treatment* must be guided by the circumstances of the swelling, and according to the causes with which it is related. Their

---

(*d*) VON WALTHER; in his Journal für Chirurgie und Augenheilkunde, vol iv. p. 390.

dispersion is always the object, and if this cannot be effected, the discharge of the collected fluid and the growing together of the cavity of the mucous sac.

1873. If the swelling be inflamed and painful, cold applications of lead wash, leeches, and rubbing in mercurial ointment must be employed; afterwards when the inflammation has ceased, or the fluid still remains, blisters kept up for some time, or rubbing in volatile ointments. If the inflammation of the mucous sac be very severe, arising from mechanical influence on a previously painless swelling of the sac, and if the swelling be very great, then usually all dispersive remedies are useless, and it must be cut into to prevent the spreading of the suppuration. Serous fluid and floccy pus escape, and the treatment is to be the same as after opening abscesses. If the swelling be, as usual, painless, volatile rubbings, long continued blisterings, warm douche baths, dispersing plasters, and the like are employed, together with which those remedies are made use of which counteract the general ill condition of the constitution; among which I have found *vinum seminum colchici* of the greatest service, especially in gouty and rheumatic complaints (*a*).

1874. If by this treatment the dispersion be not effected, and the still increasing tumour cause inconvenience, it must be emptied by a puncture or a cut, and by the introduction of tents, by irritating the inner surface of the swelling with the blunt end of a probe, by injections especially of solution of iodine, by the insertion of a seton, or by a subcutaneous cut to produce such a degree of inflammation as will put a stop to all secretion (*b*). It must not, however, be forgotten that inflammation and suppuration of a large mucous sac may produce dangerous symptoms. If the walls of the sac be very much thickened, this mode of treatment can be of no service, and it may be necessary, if the situation of the swelling permit, to remove the sac either entirely or so that its hinder walls alone remain, and be thrown off by suppuration.

The treatment of encysted dropsical swellings on the knee-cap agrees precisely with what has been just laid down, except that HEISTER's prescription (*c*), consisting of litharge ℥vj., Armenian bole ʒj., mastic and myrrh of each ʒiv., and vinegar a pint, boiled together for a quarter of an hour, and applied to the swelling on a folded cloth, four or six times a day, and keeping the patient quiet, with a moderately tightly applied bandage, will in most cases produce either the cure at once, or after the swelling has been punctured.

In the encysted swellings, (*par.* 1870,) described by **CRUVELHIER** (*d*), it is not, according to **DUPUYTREN**, sufficient merely to open them with one puncture, but two should be made, and a seton introduced. It may, however, be sufficient in most cases, to open the swelling on both sides, and to use irritating injections, as the irritation of the seton may produce very violent inflammation and fatal symptoms.

According to **LENOIR** (*e*), three mucous sacs are found on the sole of the foot, one under the heel-bone, an inch in length, the second on the under surface of the joint of the great toe, between the skin and sesamoid bones, and the third on the little toe at the same part, with a lengthening on the outer edge of the foot. The dropsy of these mucous sacs or their inflammation, with the serous exudation, may be easily taken for abscesses. If opened, they readily become fistulous, produce ill-conditioned pus, and are covered with a thickened epidermis. In inflammation, a corresponding antiphlogistic treatment, poultices, cuts, cauterization, or excision must be employed.

[I recollect seeing a case of the elder **Travers**'s in St. Thomas's Hospital, in which suppuration of the mucous sac upon the knee-cap came on very rapidly, and extended around the front and sides of the joint. The patient suffered severe symptoms of constitutional excitement, and I must confess I thought the suppuration was within the joint itself; he however thought otherwise, and directed the swelling to be freely opened; a large quantity of pus escaped, and the symptoms of irritation soon subsided. Union of the skin with the parts beneath did not, however, take place very quickly, and when all was quiet, the introduction of a probe, which ran along freely immediately beneath the skin, showed that **Travers**'s opinion was correct. She recovered perfectly, and with full use of the joint in a comparatively short time.

Irritation of the inside of these dropsical sacs by poking with a probe, setons or injections, are on no account to be resorted to, as the very probable consequence will be severe inflammation, terminating in gangrene of the sac and neighbouring parts, and high constitutional disturbance.

Occasionally it happens after the mucous sac on the knee-cap has suppurated, and either burst or been opened, that it takes on a fistulous character, and two or three or more little wounds ulcerate through the skin, which are very plaguing to the patient, and very troublesome to heal. Under these circumstances it will be found very advantageous to stuff in a little red precipitate powder, and apply ointment of the same with a bandage, keeping the patient at rest at the same time.—J. F. S.]

II.—OF DROPSY OF THE JOINTS.

(*Hydrops Articulorum*, *Hydrathrosis*, Lat.; *Gelenkwassersucht*, Germ.; *Hydrarthrose*, Fr.)

1875. *Dropsy of a joint* is a collection of serous fluid within the capsular ligament, by which it is distended into a swelling, soft, bounded by the attachments of the ligament yielding to the pressure of the finger, but without retaining any impress, distinctly fluctuating, little or not at all painful, and upon which the skin is unchanged. The swelling does not entirely correspond with the whole extent of the joint, but is greatest where the capsular ligament is most yielding and little covered. Thus, for instance, a swelling at the wrist-joint is especially distinct on its fore and hind surface, but is scarcely perceptible on its sides; at the ankle-joint it is most remarkable on the front; at the shoulder it confines itself to the front, and projects most distinctly between the deltoid and great pectoral muscle. At the knee-joint, where the disease most commonly occurs, the swelling appears in front and at the sides, when very large projects most on the inside, is divided into two parts by the knee-cap and tendon attached to it, and extends upwards beneath the muscles of the thigh. The knee-cap is thrust forward, is very movable, and after being pressed down, again rises when the pressure is removed. When the leg is bent, the swelling on the sides is larger and more tense; when the leg is extended, the fluctuation is more distinct. The movements of the limb are little interfered with in dropsy of the joint.

1876. The disease in general is slowly developed. Its *causes* may be external violence, bruisings, sprains, catching cold, rheumatic or arthritic attacks, cartilage-like bodies in the joint, and *metastasis*, whereby a slow inflammatory condition and disproportion between the secretion and absorption of *synovia* is produced. The collected fluid does not differ from common *synovia*, except that in long continuance of the disease it becomes more consistent, viscid, and of a tawny colour.

In most cases where the parts of the joint are organically altered, swelled up, thickened, ulcerated, or affected with *caries*, collections of *mucus*, or *pus*, are formed in its cavity. This condition, which has been by some described as complicated dropsy of the joint, requires only particular attention, if the disease which had produced it diminish, in which case, if the absorption of the collected fluid have not taken place under the above-mentioned treatment, (*par.* 213 and onwards,) it may require to be discharged, which I have several times done successfully at the knee-joint.

[BRODIE (*a*) observes:—"Cases occasionally (but not often) occur, in which a joint is swollen from a preternatural quantity of fluid collected in its cavity without pain or inflammation. This may be supposed to arise, either from a diminished action of the absorbents, or an increased action of the secreting vessels. The disease may be compared to the dropsy of the *peritonæum* or *pleura;* or more properly, to the hydrocele; and it has been not improperly designated by the terms *Hydrarthrus* and *Hydrops Articuli*." (p. 7.)]

1877. The *prognosis* in dropsy of a joint is usually not favourable, unless when it have arisen quickly, and have not been of long continuance, in which case its dispersion may be often easily effected. But if the disease have existed any length of time, and be very considerable, and if the ligaments have thickened, the hope of a dispersion is very slight, and puncturing the joint for the purpose of discharging the collected fluid, is an operation which may lead to the most dangerous consequences. Dropsy of a joint is also easily liable to a relapse, and when long continued, can produce organic changes of the joint, which build up new structures.

1878. The *treatment* of incipient dropsy of a joint is the same as that directed for inflammation of the synovial membrane. If the disease have existed some time, it must be the object to encourage the absorption of the collected fluid; frequent rubbing, rubbing in volatile ointments, mercurial ointment with camphor, repeated blisters frequently and at different parts applied, and long persisted in, fumigations, warm and cold douche baths, wrapping up in oiled silk, the moxa, the actual cautery, electricity, and moderate compression. The internal treatment must correspond to the cause of the disease. GIMELLE (*b*) has recommended large doses of tartarized antimonial wine as especially efficient.

1879. If the absorption of the collected fluid be not brought about by this treatment, if, on the other hand, the quantity increase, so that great pain and inability of using the limb be produced, or if there be also a foreign body in the cavity of the joint, the collected fluid must be so discharged as to prevent the entrance of the air. With this object the fluid is to be pressed against that part of the joint where the coverings are thinnest, on the knee for instance, on the inside. With the fingers of the one hand the skin is to be drawn aside, and a thin trocar, a lancet, or a bistoury, thrust into the joint, without, however, wounding the joint surfaces. After the discharge of the fluid, and the removal of the canula, if the trocar be used, in doing which the wound is to be closed with the thumb of the right hand, and the coverings held back with the fingers of the left, the skin which has been drawn aside is allowed to return to its place, so that the parallelism between the outer and inner wound is got rid of, and the wound well closed with sticking plaster.

Opening the swelling with a lancet, or bistoury, is preferable to that with the trocar, if the fluid be very thick, or if there be any little bodies at the same time present in the joint, of which the removal is also requisite.

[I can hardly think the operation of puncturing a dropsical joint is, under any circumstances, justifiable, as the inflammatory symptoms which follow a wound of the synovial membrane, even when healthy, are generally so great, and the consequences

(*b*) Gazette Médicale de Paris, vol. viii. p. 445. Paris, 1840.

so serious, and sometimes fatal, that the patient's life ought not to be endangered by such treatment. And should this practice even succeed, it is only useful for a time, as the fluid will recollect. As to the use of injections, after emptying the joint of its contents, as advised by Velpeau, and presently to be mentioned, I think it cannot be too much deprecated, and I doubt whether any English Surgeon would risk his reputation, and the safety of his patient, by a practice which must be attended with almost certain mischief.—J. F. S.]

1880. After the operation the patient must be kept quiet for ten or twelve days, and the part bathed with cold lead wash. If pain and inflammation arise, the rules recommended for wounds of joints must be followed. If these symptoms do not occur, or when they have been put aside, all those remedies must be employed, after the healing of the wound, which are capable of restoring the due relations between the secretion and absorption of the synovial fluid.

1881. The simple puncture of the dropsy of a joint rarely ever indeed produces a radical cure, as the fluid re-collects more or less quickly, and besides severe symptoms and suppurative inflammation may ensue.

To effect a radical cure, Bonnet (*a*) has employed successfully in dropsy of the knee-joint, injections of iodine; and the same has been also practised by Velpeau (*b*). After the leg has been stretched out, an assistant places his hand on one side of the joint, for the purpose of pressing the fluid towards the other, at which the puncture is to be made. The outer or inner side of the joint above the knee-cap may be chosen. The skin is then to be raised in a fold, the base of which is punctured with a trocar, which must be thrust in at least three-quarters of an inch, and so deep as that its point shall touch the front surface of the thigh-bone. A viscid transparent fluid escapes through the canula, of which only from five to seven drams is to be drawn away, that is, about a similar quantity to the quantity of fluid presently to be injected. The canula is always to be directed upwards, so that it remain full of fluid, and therefore in the injection the air is more certainly excluded. Various solutions of iodine may be used as injections; Bonnet, however, especially prefers a solution of half a dram of iodine and one dram of iodide of potash, in four drams of water (1). The quantity of fluid injected must not exceed that drawn off, and therefore, in dropsy of the knee-joint, never more than from four to five drams of fluid should be thrown in. After the injection has been made, and the canula carefully withdrawn, the puncture must be covered with sticking plaster, the limb laid in a tray, and kept perfectly still. The consequence of the injection is an acute inflammation, the running on of which to suppuration must be carefully prevented. In very great and painful swellings of the joint, from the excessive collection of fluid, it may be necessary to discharge part of the fluid by puncture, so as to lessen the symptoms.

[(1) If there be no mistake in the proportions given for this injection, which unfortunately I have not the opportunity of verifying, it must be highly caustic, and such as no English Surgeon, I think, would dare to throw into a joint, though a French Surgeon might.—J. F. S.]

III.—OF LYMPH SWELLINGS.

These have been considered in *par.* 15–18, *par.* 59–62.

IV.—OF WATER IN THE HEAD, AND CLEFT SPINE.

(*Hydrocephalus*, Lat.; *Wasserkopf*, Germ.; *Hydrocephale*, Fr.;—*Hydrorachitis*, seu *Spina bifida*, Lat.; *Rückgrathswassersucht oder Gespaltene Rückgräthe*, Germ.; *Hydrorachis*, Fr.)

1882. The term *water in the head*, or *watery head*, is usually applied to a collection of serous fluid beneath the coverings of the skull, between the skull and the brain, or in the cavities of the brain itself. According to these circumstance, it is distinguished into external watery head, (*Hydrocephalus externus*,) internal watery head, (*H. internus*,) and dropsy of the ventricles (*Hydrops ventriculorum cerebri.*)

1883. In *external watery head* the fluid may be either in the cellular tissue beneath the skin, beneath the *galea aponeurotica*, or beneath the *pericranium*. In the first case, the swelling spreads more or less over the whole head, often over the eyebrows, retains the impress of the fingers, and is specially characterized as *œdema*. In the second and third cases, be the swelling more or less spread, yet it never reaches to the eyelids. It is incorrect to apply the term *hydrocephalus* to this disease. It requires merely the ordinary treatment of *œdema*, the use of dispersive applications in connexion with rubbing and moderate compression, and if these be insufficient, the discharge of the fluid by cutting into the swelling.

Whether a partial collection of water under the *galea aponeurotica* actually exist, in which the swelling depending on it may be confused with other diseased conditions, has been already doubted.

1884. The *collection of water within the cavity of the skull* appears alone to deserve the name *hydrocephalus*. The collection of water between the membranes of the brain and the skull, is most properly distinguished as *hydrocephalus externus*, and that in the ventricles of the brain as *hydrocephalus internus*, or *hydrops ventriculorum*. Both conditions may agree together in being *congenital vices of formation*, the consequence of the staying of the *fœtus* at an earlier stage of development. *Hydrocephalus*, however, is frequently first developed at a longer or shorter period after birth, and mostly without any very decided cause. The watery head now to be considered may be distinguished as *hydrocephalus chronicus*, from *hydrocephalus acutus*, which quickly ensues, in consequence of inflammation.

The primary existence of external *hydrocephalus* is indeed denied by many, and it is asserted that the water only reaches the surface of the brain by a tearing of the cavities (*a*); it is, however, possible, that the water may be originally secreted as well on the outer as on the inner surface of the brain (*b*); for according to Magendie's (*c*) observation, there is naturally a watery fluid between the arachnoid coat and the vascular coat of the spinal marrow, which communicates with the ventricles of the brain by an opening in the bottom of the fourth ventricle. The same applies to the fluid between the *membrana arachnoidea* and *pia mater* upon the surface of the brain. External *hydrocephalus* is at all events a rare circumstance; it is not easily distinguishable from internal *hydrocephalus*, and resembles it in its symptoms, and the treatment it requires.

(*a*) Monro, Observations on the Eye, the Ear, and the Brain, p. 38.

(*b*) Meckel; Handbuch der pathologischen Anatomie, vol. i p. 263.

(*c*) Journal de Physiologie, vol. vii. p. 1. 1827, Jan.

1885. In the congenital internal *hydrocephalus*, which is developed at no very determinate period of pregnancy, as also in that occurring afterwards, the walls of the brain are considerably distended by the collection of water in the ventricles, are thinned, and the convolutions unfolded; the partition of the ventricles (*septum lucidum*) is destroyed, and their internal lining generally thickened; yet, however, with this great thinning and as it were membranous extension of the brain, its gray and medullary substances are still distinguishable. In proportion as the collection of water becomes greater, the still yielding and not yet firmly connected skull-bones spread out, and the head acquires an enormous size. It is uncommonly broad, especially in the region of the ossifying points, because the bones, specially those on the sides, are thrust asunder by the water. The face has no longer an oval, but a triangular form, the forehead projects considerably over the orbits, and there is a remarkable disproportion between the size of the face and skull. The skull-bones form slowly, and are connected only by a number of intermediate bones. The membranes enclosing the water are not unfrequently torn during labour, the water discharged, and the coverings of the destroyed brain, for the most part, fall together.

1886. If in great distension of the skull some parts be more yielding than others, or the water sink from the fourth ventricle, between the *pia mater* and *tunica arachnoidea*, into the canal of the spine, by which the cartilaginous plates forming, previous to its perfect ossification, the hind portions of the *vertebræ* are outspread, there are produced elastic fluctuating swellings covered with a thin, sometimes transparent, skin, of various size, and forming the disease called *Cleft Spine* (*Spina bifida.*) These may be diminished by compression, upon which ensue *coma*, convulsions, palsy, and the like, Several such swellings may occur at the same time, so that the fluid may be driven from one to another. Their base is sometimes broad, sometimes has a neck, and on examination with the finger the edge of the opening in the bone, by which the fluid escaped, is felt distinctly, its shape round and regular on the skull, and oblong on the spinal column, where it is formed by a double row of spinous processes. These swellings may be seated at any one part of the skull, where the bones are separated by the sutures, especially on the forehead, on the sides, and on the back of the head; sometimes several exist together. These swellings are noticed in the spine, most commonly in the lumbar region, more rarely in the back and neck. Very rarely do several exist at the same time in the spine.

If a close connexion and co-existence be assumed between internal *hydrocephalus*, watery bags on the head and cleft spine, (*hydrorachitis, spina bifida,*) which opinion is confirmed on numerous grounds, it cannot, however, be denied that a primary collection of water in the membranes enveloping the spinal marrow, may exist without water in the head. Although the seat of the water be not always the same, it is, however, probable that it most commonly collects between the vascular and arachnoid coats. (*par.* 1884.) Gall noticed an example in a child eighteen days old with a cleft of the second, third and fourth lumbar *vertebræ*, and a collection of water within the arachnoid coat; and in the whole length of the spinal marrow, two lateral, smooth, slightly distended canals, which were perfectly closed, and entirely unconnected with the collection of water (*a*).

[(1) A very good case of the watery sac here described, is given by Chesman, of Sheffield (*b*), in a child three years and a half old:—"Over the left frontal protube-

(*b*) Prov. Med. and Surg, Journ., vol. vii. 1844.

rance was a tumour of the size of a large orange, membranous, but having in its centre a small portion of thin bone. This membrane arose from a projecting portion of bone, almost circular, whose diameter was three inches and a half, and contained about half a pound of serum; when this was suppurated, it appeared as if there was a shell of bone below, which was not complete, as the fluid run from this cell into the cavity of the skull. The roof the orbit was nearly convex. On puncturing the right side of the anterior fontanelle, about five pints of serum were drawn off. The body was of a rickety appearance and much emaciated, and there was a *spina bifida* of the size of a hen's egg in the lumbar region. The child had possessed all its faculties until a day or two previous to its death, but generally lay on a sofa with its head raised. Until five months of age the head had been normal, but then increased." (p. 564.)]

1887. The mischiefs produced by *hydrocephalus* and *spina bifida* in the functions of the brain and spinal marrow, are not always the same. Most commonly children born with water in the head die soon after birth, either in consequence of the disease itself, or the damage which the head suffers during delivery; in rare cases, however, they reach a more or less advanced age, and the head acquire an enormous size. Notwithstanding the diminished size of the brain, its functions are not always proportionally lost. Although the functions of the intestinal canal be in general natural, the nourishment of the body otherwise is affected, so that it is extremely thin and backward in its development. In those cases in which *hydrocephalus* is accompanied with watery bags, the above-mentioned mischiefs are usually slighter, and scarcely observable. In *spina bifida*, indeed, the condition of the spinal marrow is, for the most part, altered; it is thinner, is dissolved into a watery substance, studded with watery bladders, and at the seat of the cleft entirely deficient; it is, however, rarely altered further than at the seat of the cleft, and not always in the same degree. Symptoms of *hydrocephalus* usually accompany *spina bifida*, great wasting, weakness of the lower limbs, involuntary discharge of the urine and stools, spasms, convulsions, and so on. The larger the swelling, and the nearer it is to the head, the more violent generally are the symptoms. Mostly children so affected die soon; they, however, in rare cases, live a shorter or longer time. With *hydrocephalus* and with *spina bifida* other misformations are frequently connected, for instance, hare lip, cleft palate, club foot, and the like, whence it decidedly follows that they must be considered as the consequence of an arrested development (*a*).

Fisher's (*b*) observations on the origin of *spina bifida* are very interesting; he found in two cases a *union of two or more sacral ganglions, the passage of their respective nerves through the sheath in one bundle*, and *the union of the end of the spinal marrow with the walls of the sac.* I have fully verified this statement, in a case in which death followed some time after puncture. Fisher hereon founded the following opinions:—*first*, that the union of the sacral ganglions depended on primary irregularity, from which arose the anomalous division of the corresponding nerves between the ganglions and the spinal marrow; *second*, the growing together of the spinal marrow with the sheath prevented the ascent of the marrow in its natural position, and to it is to be ascribed the irregular way in which the nerves are inserted into the spinal marrow; *third*, the union of the ganglions may, in a degree, be ascribed to the development of a process, by which the neighbouring ganglions, in many cases, themselves of natural form, unite with each other; and the general existence of this deformity at the lower part of the spinal column depends on the relative position of the sacral ganglions which lie in the sacral canal, whilst those of the other spinal nerves are in the intervertebral holes; *fourth*, the incomplete form of the hinder wall of the vertebral column is rather to be
